The use of the so-called "universal donor" (Group O or Type IV) may be distinctly dangerous if the recipient belongs to another blood group, because such a donor has in his serum the anti A ( $\alpha$ ) and anti B ( $\beta$ ) agglutinins. Witelsky, Klendshoj and Swanson<sup>22</sup> set about the task of isolating the A and B specific substances and then adding them to blood containing anti-A and anti-B agglutinins, thus neutralizing the possible ill effects of transfusing Group O blood. Both the A and B substances are carbohydrate-like and similar to the complex carbohydrates that are recognized as the bearers of the type specificity of pneumococci and other organisms. Addition of small amounts of these substances to blood for transfusions effectively removed the anti-A and anti-B agglutinins and did not cause reactions. These substances are not at present commercially available. They have been found of value not only in making Group O blood entirely compatible but also in neutralizing the A and B agglutinins of M, N and Rh testing serums.

The moral of this section on the blood groups might be stated as follows: transfuse only when absolutely necessary and only after extremely careful compatibility tests have been performed by responsible, experienced persons.

\*These may be obtained from the Blood Betterment Association, New York City and from Lederle Laboratories Incorporated, Pearl River, New York.

## WHITE BLOOD CELLS

*Basophils*

Doan and Reinhart<sup>23</sup> present a carefully documented discussion of the basophil (basophil granulocyte). They state that "of all the cells found in normal blood least, perhaps, is known at the present time about the basophil type of granulocyte." They cite cases indicating a possible "primary progressive specific hyperplasia of basophil granule leukocytes."

*Infectious Mononucleosis*

This very common, and rarely diagnosed, condition continues to be the subject of numerous reports. In a paper by Werlin, Dolgopel and Stern,<sup>24</sup> the possible confusion of the condition with diphtheria is discussed. In 14 of 21 cases admitted to the Willard Parker Hospital in New York City, the clinical picture was considered sufficiently suspicious of diphtheria to warrant the administration of diphtheria antitoxin on admission. The authors state:

. . . . The diagnostic difficulty was further complicated in 7 of these cases by the presence of non-toxic diphtheria-like bacilli in the throats of 6 patients and in the nose of 1 patient. The negative toxicity tests of the isolated bacilli, the hematologic picture, the positive heterophil antibody test and the lack of response to the diphtheria antitoxin helped in establishing the correct diagnosis.

Cerebral complications are quite frequent, and as Thelander and Shaw<sup>25</sup> point out, severe headache is often an early and prominent symptom. I have recently seen a number of cases in which the diagnosis of "aseptic lymphocytic meningitis" or "choriomeningitis" was made. To be sure, the spinal fluid revealed a lymphocytosis, but there was a marked lymphocytosis in the peripheral blood and the sheep-cell agglutination test was positive. Sadusk<sup>26</sup> directs attention to the temporarily positive serologic tests for syphilis, which occur in approximately 15 per cent of reported cases (only in some series, it should be noted) and indicate that a positive Wassermann or Kahn reaction is likelier to occur in the presence of a rash.

Smith<sup>27</sup> directs attention to what he calls "infectious lymphocytosis." In young patients, a transient lymphocytosis without other symptoms or signs, or a more prolonged lymphocytosis following infections of the upper respiratory tract, is not uncommon. Smith contends that these cases are frequently confused with infectious mononucleosis, but that they should be differentiated from them by the essentially normal, mature character of the lymphocytes, and by the negative heterophil reaction. This differentiation is significant, since otherwise an underlying respiratory or other infec-

tious process might be missed. Essentially, Smith's infectious lymphocytosis is simply the lymphocytic reaction commonly seen in any chronic smoldering infectious process, and does not indicate a hitherto undescribed condition. What is more, infectious mononucleosis might best be called "infectious lymphocytosis," since the cellular reaction is primarily lymphocytic and not monocytic. Acute cases of so-called "glandular fever" that resemble mononucleosis in every respect but have negative heterophil reactions are occasionally seen. Are these due to a different etiologic agent than that causing infectious mononucleosis, or are they simply heterophil negative? Since the etiologic agent has not yet been discovered, this question is difficult to answer.

*Leukocytic Reactions, including Leukopenia*

The sulfonamide drugs continue to prove a fertile source for the development of various reactions involving both the red cells and the leukocytes, although with the use of the newer drugs, sulfathiazole and sulfadiazine, the reactions seem to be distinctly lessened. Rinkoff and Spring<sup>28</sup> report 8 cases of either severe leukopenia or agranulocytosis following the use of sulfanilamide or sulfapyridine, but of 51 treated with sulfathiazole, none developed a toxic reaction. However, Kennedy and Finland<sup>29</sup> report a case of fatal agranulocytosis following the use of sulfathiazole. Plum and Thomsen<sup>30</sup> compared the agranulocytosis caused by amidopyrine with that induced by the sulfonamides and concluded that an accompanying anemia was much commoner with the latter drugs and was often associated with a rash, although severe throat lesions were less frequent. The mortality rate was distinctly less in the sulfonamide-treated cases (67 per cent). Occasionally, marked leukocytosis and even a leukemoid reaction may occur with the sulfonamides. These are usually either in association with or preceding a definite hemolytic reaction. Whether or not some of the cases of acute leukemia seen following the use of sulfonamides have any relation to the drug or are coincidental cannot be stated for certain, although since the drugs are given for almost every fever, coincidence is more than likely.

Lawrence<sup>31</sup> describes the various abnormal physiologic conditions that may result in leukopenia, grouping them as follows: those due to diminished manufacture of white blood cells (including aplasia and maturation arrest); those due to increased elimination of white blood cells; those due to an increased rate of destruction in the peripheral blood; those due to redistribution of

the leukocytes in the vascular channels; and those due to redistribution of the leukocytes in the body as a whole, as in the leukopenic phases of certain cases of leukemia. He makes a plea for a more physiologic understanding of the various causes of leukopenia. An interesting type of severe leukopenia said to be caused by an increased destruction of leukocytes by the spleen is described by Muether and his associates.<sup>32</sup> This condition, first described in a systematic way by Doan,<sup>33</sup> may be acute or chronic, and may even simulate agranulocytosis. It is often accompanied by splenomegaly, and at times by slight hemolytic jaundice. The bone marrow is hyperplastic. Splenectomy has resulted in dramatic cures. The interpretation of both the Columbus and the St. Louis workers is that the spleen destroys the leukocytes by phagocytosis. It is my belief<sup>34</sup> that splenic enlargement often causes an increase in the normal inhibitory effect of that organ in the marrow, with the result that the marrow becomes crowded with leukocytes, which are apparently prevented from being delivered to the circulating blood. Splenectomy may result in a resumption of the normal delivery mechanism. In any event, splenic leukopenia and granulocytopenia, often of striking degree, may be secondary to splenomegaly and relieved dramatically by splenectomy.

#### *Reactions to Benzol and Related Chemicals*

An increasing interest is being shown in the reactions of benzene chemicals on the blood-forming organs. Schwarz and Teleky<sup>35</sup> state that the blood picture in chronic industrial benzene poisoning is the result of a balance between destructive and regenerative forces. Instead of the classic anemia, leukopenia and thrombopenia, temporary erythrocytosis, erythroblastosis, leukocytosis with immature white cells and even leukemia may develop. Any change from the normal should be an immediate indication for the removal of the worker from the source of exposure. It is recommended that blood examinations be made monthly in workers using benzene, and every four to six months in those using related chemicals. Goldwater,<sup>36</sup> in a study of 332 workers exposed to benzol fumes in rotogravure industry in New York City, observed that anemia, macrocytosis and thrombocytopenia were the commonest abnormalities, whereas leukopenia and neutropenia were rather unusual. Not infrequently, relatively high hemoglobin values associated with elevations in the mean corpuscular volume were present. In another paper, Goldwater and Tewksbury<sup>37</sup> made a follow-up study of rotogravure workers who had developed blood changes as the result of exposure to benzol and who had then been safe-

guarded from the hazard. Toxic effects were present in some cases for at least two years. Recovery was manifested by an increase in red-cell count, a decrease in red-cell size and an increase in the platelet count. The usual forms of anti-anemic treatment appeared to have no effect in hastening recovery. Hamilton-Paterson<sup>38</sup> studied workers exposed to benzol in the rubber industry. In this series of cases, leukopenia was the commonest finding, but leukocytosis and even leukemia occasionally developed.

All these reports confirm an earlier one by Hunter<sup>39</sup> in which similar findings were made. The possibility that prolonged exposure to low concentrations of benzene might produce leukemia was first broached in this paper, and should be seriously considered. Careful histologic studies of the bone marrow and other blood-forming organs were made by Mallory, Gall and Brickley,<sup>40</sup> who showed the very variable changes—aplastic, hypoplastic, proliferative and even leukemic—that might develop. These changes depended on the intensity and duration of exposure, hyperplasia following prolonged exposure and hypoplasia of either short or long contact. The authors pointed out that although the evidence indicating that chronic exposure produces leukemia was still incomplete, it is nevertheless accumulating and worthy of serious consideration. Rawson, Parker and Jackson<sup>41</sup> state that all their 6 cases that were diagnosed as "agnogenic myeloid metaplasia" and were available for study gave a history of exposure to industrial solvents, "high-test" gasoline, carbon tetrachloride, paint remover or benzol.

#### *POLYCYTHEMIA VERA*

Primary, idiopathic or true polycythemia is a disease of the bone marrow in which striking hyperplasia of all the elements—erythroblastic, leukocytic and megakaryocytic—continues for many years. This results in great increases in the red cells, leukocytes and platelets of the blood and, finally, in a great overdistention of the entire circulation. The cause of the continued hyperplasia remains obscure, although the most attractive theory is that of anoxia of the marrow, with resultant stimulation to erythropoiesis. It should be noted, however, that anoxia (such as that at high altitudes) causes only erythrocytosis, the platelets and granulocytes remaining normal in number. Davis<sup>42</sup> showed that the oral and subcutaneous administration of both ephedrine and amphetamine (Benzedrine) caused polycythemia (erythrocytosis) in dogs and rabbits, perhaps through vasoconstriction of the vessels of the bone marrow, with resultant anoxia and stimulation of erythropoiesis. This effect occurred in both

normal and splenectomized animals and appeared to be due to a real influence on red-cell production.

The extreme viscosity of the blood, in addition to the great overdilatation of the entire circulation, leads to the development of a sluggishly moving mass of blood. Offhand, it seems that the work of the heart should be increased. However, measurements of the cardiac and respiratory function in 3 relatively young patients by Altschule, Volk and Henstell<sup>13</sup> revealed normal values, and the conclusion was made that the slowing of the blood flow was due to increased capillary resistance because of the greatly increased viscosity, which, with the slow blood flow, the greatly increased platelet count and the early onset of arteriosclerosis, is of course conducive to the development of thrombosis.

Another complication that has recently received increasing attention is that of sclerosis of the marrow usually associated with a bone-marrow type of cellular proliferation (myeloid metaplasia) in the spleen. In last year's progress report,<sup>44</sup> reference was made to a number of articles in which this end-result condition was discussed. That there is an "agnogenic myeloid metaplasia"<sup>45</sup> of the spleen, without reference to polycythemia, hemolytic anemia or involvement of the bone marrow by neoplasm, leukemia, Gaucher's disease and so forth, is questionable; nor does it seem desirable to make of this condition a separate entity. Furthermore, that bone-marrow proliferation develops in the spleen in response to bone-marrow destruction elsewhere or to unusual bone-marrow stimulation, as in severe hemolytic anemia, has been known for many years; its rediscovery under a new guise is interesting but perhaps confusing. It is also likely that many of the cases of chronic myelogenous leukemia reported following polycythemia are in reality examples of this "burnt-out" state of polycythemia, the leukocytic proliferation being unusually prominent.

In the treatment of polycythemia, all the symptoms may be quickly relieved by reducing the blood volume to normal and keeping it so. This is done by semiweekly venesections of blood for three to five weeks (depending on the case), and by the use of a diet low in iron.<sup>46</sup> On the face of it, this appears to be a more physiologic method of treatment than the use of hemolytic drugs (phenylhydrazine), a toxic drug such as lead, as suggested by Falconer,<sup>47</sup> or radioactive phosphorus.<sup>48</sup> Patients with polycythemia are relatively healthy and live for many years. The use of harmful or potentially harmful drugs seems therefore undesirable.

## HEMORRHAGIC DISEASES

The clotting of blood in blood vessels is a function of the enzyme-chemical factors, thromboplastin-prothrombin-fibrinogen, of the platelets and of the blood-vessel wall. Failure of clotting occurs in the presence of a defect in any of these three mechanisms. An analysis of 355 autopsy cases that showed one or another of these disturbances is reported by Perlman and Fox.<sup>49</sup> The suggestion is made that the term "hemorrhagic diathesis" be used, qualified by the phrase "on the basis of" damage to or weakness of the capillary endothelium, deficiency of the clot-forming elements or faulty clot retraction due to thrombocytopenia.

### *Deficiency of the Clot-Promoting Elements*

Quick<sup>50</sup> gives an excellent and detailed review of the hemorrhagic disorders due to defects in the coagulation mechanism of the blood. These may be associated with diminished prothrombin, calcium deficiency, thromboplastin deficiency, fibrinogen deficiency and, finally, the presence of anticoagulants. Ferguson<sup>51</sup> also gives a summary of his and other work on the blood-clotting anomalies in the hemorrhagic diseases. Both authors rule out calcium as having any importance in these conditions. The original reviews should be consulted for specific information on these subjects.

*Hypoprothrombinemia.* The earlier work on vitamin K deficiency and its bearing on hypoprothrombinemia has been cited in previous reviews. Recent articles have extended the groundwork already laid. The value of protecting the newborn infant from the effects of a low prothrombin level by giving the expectant mother vitamin K from five to twenty-eight days prior to delivery is pointed out by Valentine, Reinhold and Schneider.<sup>52</sup> About three quarters of the infants of untreated mothers developed a low prothrombin level within forty-eight to ninety-six hours after birth, whereas infants of protected mothers showed no such fall. It is further to be noted that one of the causes of cerebral hemorrhage of the newborn may be hypoprothrombinemia, and that the prothrombin level of the infant may be made normal by the simple injection of one of the parenteral preparations six or eight hours before delivery. That liver damage results in a diminution in the prothrombin is by now well known. Lucia and Aggeler<sup>53</sup> tried to correlate the various liver-function tests with the diminished blood prothrombin in a series of cases. No definite correlation could be determined, although some differentiation between hepatic jaundice and obstructive jaundice could be worked out by the administration of vitamin K. In the presence of hepatic disease, the prothrom-

bin clotting time could not be materially altered. Similar findings and the development of a liver-function test based on this procedure are made by Lord and Anders<sup>54</sup> A hemorrhagic agent resulting in an increased prothrombin time has been studied by Bingham, Meyer and Pohle.<sup>55</sup> This material, which was isolated and crystallized at the University of Wisconsin Agricultural Experiment Station, has been shown to be a dicoumarol. Synthetically prepared, it produced prolongation of the prothrombin and coagulation times, when given to dogs and human subjects. It is suggested that the material may prove to have a valuable place in clinical medicine as an anticoagulant to replace heparin

**Hemophilia.** Despite vigorous investigation, no very striking advance has occurred in either the pathogenesis or the treatment of hemophilia. The researches of Taylor and his collaborators at the Thorndike Memorial Laboratory, Boston City Hospital, cited in previous reviews, indicated that something was lacking in the globulin fraction of the plasma. In the meantime, the old theory that hemophilia is due to a diminution in thromboplastin formation from unusually resistant platelets has been espoused again, chiefly by Quick,<sup>56</sup> Ferguson<sup>51</sup> and Howell.<sup>57</sup> Quick described a new diagnostic test for hemophilia based on the diminished production of thromboplastin from abnormally resistant platelets. He found that the coagulation time of ovalated hemophilic plasma subjected to high centrifugation is markedly longer than that of slowly centrifuged plasma. With high centrifugation, the intact platelets are thrown down, leaving a plasma poor in both free and potentially free thromboplastin. Ferguson suggests that hemophilia is a deficiency in the plasma content of a new thromboplastic enzyme, the function of which is to mobilize calcium and cephalin for the conversion of prothrombin to thrombin. Howell considers one real difference between normal and hemophilic blood to be that the latter contains less thromboplastin in its plasma.\*

Although most of the complications of hemophilia cannot be controlled except by the transfusion of fresh blood or plasma, an advance has recently been made in the control of bleeding from a local exposed area, such as a tooth socket. This has come out of the investigations of Parfentjev,<sup>58</sup> who by purification of the globulin fraction of rabbit plasmas obtained a substance capable of producing clotting when added in very small amounts to normal plasma or blood. This material was found to act directly on fibrinogen and could clot

prothrombin-free plasma. Parfentjev's results were confirmed by Taylor, Lozner and Adams,<sup>59</sup> who demonstrated that the material was a pseudoglobulin possessing true thrombic activity and differing from thromboplastin. It could be prepared in dry, stable form. Lozner, MacDonald, Finland and Taylor<sup>60</sup> found that one part of dry powdered rabbit thrombin could clot 60,000 parts of 0.25 per cent citrated blood within three seconds, and was of distinct value in the control of hemorrhage from small wounds both in normal subjects and in those with various hemorrhagic diatheses, including hemophilia. It is probable that this material will shortly be commercially available.

Although heparin, which is an anticoagulant, is somewhat outside the scope of this review, one should mention the monograph on this subject by Jorpes<sup>61</sup> and a recent symposium<sup>62</sup> on heparin and thrombosis. Ferguson and Glazko<sup>63</sup> have also contributed a short review.

### *Thrombocytopenic Purpura*

The controversy still continues about whether the bleeding in thrombocytopenic purpura is due solely to a deficiency in the blood platelets or to a vascular factor. MacFarlane,<sup>64</sup> in a comprehensive and critical review of hemostasis, concludes that the platelets, aside from their role as accelerators of blood coagulation and clot retraction, do not have an essential part in the hemostatic mechanism, but that the contractility of the blood-vessel wall is all important. In idiopathic thrombocytopenic purpura, the significance of the platelet count is denied, but the capillaries of the nail bed are very irregular and distorted. These observations hardly agree with the almost instantaneous response to splenectomy and the striking changes of the megakaryocytes in the marrow before and after the operation. Rabinowitz<sup>65</sup> contributes yet another theory, namely, that the liver function in the disease is somehow impaired. The oral administration of an amino acid, methionine, is stated to be effective in controlling the spontaneous bleeding and the defective clot retraction, and to be "of inestimable value in the management of both the acute and chronic stages of the disease." In view of the many substances that have been recommended in the treatment of thrombopenic purpura, the results with methionine must await confirmation. Elliott and Whipple<sup>66</sup> conclude that the role of the spleen in the disease is active and important, although the capillary factor is also of consequence. It should be remembered, however, that the pathognomonic feature of idiopathic thrombopenic purpura is the great reduction in the blood platelets, and that the disease is almost always cured, capillaries or no capillaries, by

\*The work of these three investigators contradicts that of Taylor and his associates which indicates that platelets have little if any relation to the clot-forming globulin substance.

splenectomy, which results in a dramatic and sustained rise in the platelet count.

The exact relation of the spleen to the disorder is not entirely clear, although it is my contention that some sort of functional abnormality develops there and causes an unusual inhibition of platelet formation from megakaryocytes in the bone marrow. This is based chiefly on bone-marrow studies before and after splenectomy. Another method of approach is that of the injection of splenic extracts prepared from splenectomized cases. Troland and Lee<sup>67</sup> reported a remarkable reduction in the platelet count of rabbits when an active extract ("thrombocytopen") was injected. A number of investigators have failed to confirm this apparently clear-cut finding; on the other hand, Rose and Boyer<sup>68</sup> and, more recently, Otenasek and Lee<sup>69</sup> offer complete confirmation in several cases.

What is clear in the disease is the dramatic effect of splenectomy. With a patient bleeding acutely from all the orifices and into the skin, it is first essential to rule out acute leukemia or other disease and at the same time rule in the idiopathic form of thrombopenic purpura. The blood picture does not always permit this differentiation, and for this reason, it is my custom always to perform a sternal puncture. If the marrow shows no evidence of leukemic or other proliferative lesion but presents large numbers of megakaryocytes without platelet formation, immediate splenectomy is recommended, because if the natural procrastination is allowed to win out, a fatal hemorrhage into a vital organ—usually the brain—may well occur. In the past year, I have seen 3 such cases, in which for various reasons the decision for splenectomy was delayed; in the meantime, while the discussion was continuing, the patient in each case had a cerebral hemorrhage and died. In contrast to this, in a recent dramatic case, a young woman had an appendectomy and almost simultaneously began to bleed into the abdominal wound and the skin, and from all the orifices. Despite several transfusions, her condition soon became desperate. There was marked anemia and tachycardia. After study of the blood and marrow indicated an idiopathic thrombopenic purpura, immediate splenectomy was recommended despite the obvious surgical risk and the recent abdominal operation. Splenectomy resulted in quick cure. In this case, the almost 100 per cent mortality with watchful waiting was balanced against the perhaps 30 to 50 per cent mortality of splenectomy.

### Vascular Purpura

Bleeding into the skin or mucous membranes may take place in the presence of normal platelets and under conditions of capillary damage induced by infectious, toxic, allergic or unknown agents. The "devil's pinches" so common in women and the purpura of nephritis and of the Schönlein-Henoch syndrome are of this vascular type. A deficiency in ascorbic acid leads to the capillary hemorrhages so common in scurvy. Vitamin C has been tried for many types of vascular purpura, but it is completely without effect except when a deficiency in that vitamin is present. Recently, vitamin P or citrin (Szent-Györgi) derived from lemon juice or orange peel has been suggested as a regulator of vascular permeability and, hence, as an effective agent in the treatment of vascular purpuras. Kugelmass<sup>70</sup> reported good results with this material in the treatment of 2 cases of allergic purpura, 1 of infectious purpura and 1 of nutritional purpura. In a case of purpura hemorrhagica occurring after arsenic therapy, Gorrie<sup>71</sup> reported quick recovery following treatment with vitamin P (Hesperidin, Glaxo). These results deserve further study before their real value is determined.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28101

#### PRESENTATION OF CASE\*

A twenty-three-month-old Portuguese-American girl was admitted to the hospital because of dark-colored urine.

One week before entry, she began to void dark urine and to pass light-colored stools. For two days previous to entry, she was feverish, and it was noted that the abdomen was enlarged. She had no vomiting, diarrhea or other systemic or constitutional symptoms.

The family history was not contributory. The patient was a full-term, normally delivered infant who had received an adequate diet and had undergone normal growth and development.

Physical examination revealed a well-developed and well-nourished child whose breathing was rapid and shallow, but regular. There was moderate icterus of the skin and scleras. Shotty lymph nodes were palpable bilaterally in the cervical and inguinal regions. The heart and lungs were normal. The abdomen was protuberant and tense. The liver edge was palpable at the level of the umbilicus. There was no spasm or tenderness. The spleen and kidneys were not palpable, and no fluid wave was obtained. Examination of the nervous system was negative.

The temperature was 99.6°F., the pulse 140, and the respirations 28.

Several samples of urine were deep brown, with moderate amounts of bile. There were slight traces of albumin on several occasions, with repeatedly negative sediments. The urine was free of urobilinogen. Examination of the blood showed a red-cell count varying between 3,560,000 and 5,100,000 with corresponding hemoglobin determinations between 69 and 83 per cent, and white-cell counts ranging between 13,000 and 19,000 with a normal differential. The blood Hinton reaction was negative. Repeated blood cultures were negative. The venous clotting time was 7 minutes, with a normal clot retraction. The fasting blood sugar was 182 mg. per 100 cc., and the blood cholesterol 268 mg. The van den Bergh reaction was biphasic,

and the nonprotein nitrogen of the blood serum was 28.7 mg. per 100 cc. The stools were constantly clay colored. Repeated brucellergin tests and tuberculin tests in dilutions up to 1:10 were negative. Investigation of the sputum for fungi was negative.

Roentgenograms of the skull and extremities were negative, and those of the lungs showed a moderate amount of diffuse, fine, mottled peribronchial infiltration. On repeated examinations of the chest, the infiltration became more diffuse over a two-week period and then remained unchanged until three months later, when the lung fields became more vesicular and emphysematous.

The patient remained in the hospital for four months. During this time, she ran an intermittent low-grade temperature, with occasional bouts of fever up to 103°F. Her condition remained essentially unchanged except for a slight but steadily progressive loss of weight. Jaundice persisted. Two and a half weeks after entry, the spleen became palpable. Three and a half months after entry, a lymph-node biopsy was interpreted as showing chronic nonspecific lymphadenitis. Four months after admission, an exploratory laparotomy was performed. Although the patient apparently withstood the procedure quite well, death occurred on the first postoperative day.

#### DIFFERENTIAL DIAGNOSIS

DR. HARRY L. MUELLER: We might pause for a moment to remark that this is a Portuguese infant and that the onset of the jaundice may therefore have been at an earlier date than was suspected, because these children are rather apt to have dark, olive skins.

This patient was in the hospital for four months. If she had a progressive constitutional disease, it is surprising that her condition did not become much worse during that period than is apparent from this history.

Painless, persistent jaundice, with clay-colored stools, and the large liver persisting for four months in a two-year-old infant certainly make me believe that there was some unusual cause of obstruction to the biliary drainage system. The fact that the child exhibited no gastrointestinal symptoms at an age when almost any disease is accompanied by such symptoms makes me quite confident that there was no disease in the gastrointestinal tract. I am ruling out catarrhal jaundice, which is the common cause of jaundice in a child, although quite rare at this age, because of the long course and the fact that there were no gastrointestinal symptoms.

We must assume a point of obstruction and select

\*This case is presented through the courtesy of the Children's Hospital, Boston.

the most likely point and cause for that obstruction. I should consider the portal fissure the most probable position, and it appeals to me to place Hodgkin's disease in that region. The loss of weight, fever, pulmonary lesion and apparently normal blood picture, as well as the later development of splenic enlargement, are all consistent with Hodgkin's disease. This condition may present an apparently normal blood picture, occasionally has a leukocytosis, and may have a relative lymphocytosis, which might explain why the differential count appeared normal, although there was a leukocytosis. The negative biopsy does not to my mind rule out Hodgkin's disease. Another lesion that should be given serious consideration is lymphosarcoma in the same region, although the course of the disease does not fit in so well. Lymphosarcoma is prone to metastasize to both the bronchial and the mediastinal lymph nodes, and such metastasis must be considered. Tuberculosis in this position does not often cause pressure symptoms, and with a negative tuberculin reaction and the lack of any report of calcification I should be inclined to rule that out. We might stop here and get an interpretation of the x-ray films.

DR. AUBREY O. HAMPTON: This is a very unusual pulmonary picture. In the first examination, it looks very much like miliary tuberculosis. In fact, that would be my unhesitating opinion if I saw this film alone. I should think that it was in the terminal stage and that the patient would die much sooner than in three months—in fact, three days would be more likely. However, the pulmonary picture changes markedly in three months and shifts into something entirely different. At first, there was a miliary process in the lung, and at the last examination there is what appears to be pulmonary fibrosis with emphysema. I have not seen pulmonary fibrosis that started out as a miliary lesion. In some respects, the progression is like silicosis, which can begin with a miliary lesion, and later shifts into extreme fibrosis with blebs, but a child does not have silicosis. The marked increase in the anteroposterior diameter of the chest is like emphysema. The abdomen is rather unusual. Here is the shadow of what appears to be the liver. It is unusually distinct in the lateral view; it is not so distinct in the anteroposterior view, but it is certainly enlarged. I think that the spleen is represented here—moderately enlarged, not markedly. That film was taken four months before death.

DR. MUELLER: Can you make out any kidney shadows?

DR. HAMPTON: The right kidney appears normal in size and shape. I do not see the left.

DR. MUELLER: Is there any question of a retroperitoneal mass?

DR. HAMPTON: No; and I do not believe that lymphoma would produce this chest picture unless a great deal of radiation had been given.

DR. MUELLER: Could Hodgkin's disease regress as the result of frequent x-ray and fluoroscopic studies?

DR. HAMPTON: This is a very diffuse lesion. All the lobes are involved alike. I do not believe we could produce that picture with radiation if we tried.

DR. MUELLER: Is there any evidence of enlargement or calcification of the mediastinal lymph nodes?

DR. HAMPTON: No.

DR. MUELLER: I do not know much more than I did before we started except that I am a little more confused. I am convinced that this child had an obstructing lesion somewhere in the biliary drainage system. We must try to couple it with the pulmonary process and decide whether the primary lesion was in the lungs or in the abdomen.

Malignant tumors in infants of this age have a very rapid course, and I do not believe that the child would have been in such good condition at the end of four months if the metastases had been so widely distributed. There is also no evidence of a palpable mass, although that could be tucked up under the edge of the liver. Stone seems very unlikely, with the other aspects of the case, and of course is rare in a child of this age. I do not believe we have to consider it seriously. Foreign body should always be considered in children. Any foreign body that would obstruct the biliary tract would certainly cause some gastrointestinal symptoms. Parasites should perhaps be more seriously considered than I had thought previously. Distoma and ascaris can both invade the common and intrahepatic ducts, as well as the cystic, and can cause obstruction. I should expect stool examinations to pick up some evidence of that. There is nothing in the record to show that the stool examinations were made with that in mind. One other parasite that ought to be considered is the hydatid cyst. The Portuguese are sheep herders. There is no mention in the record that these people had a sheep dog, but a hydatid cyst impinging on the hepatic duct could give a course similar to this. What type of lesion might result in the lungs from ruptured hydatid cyst, I am frank to say I do not know, but I do not believe that has to be considered seriously. Tumors of the pancreas and gastrointestinal tract and kidney are rather unlikely because they would present other gastrointestinal or urinary signs and symp-

toms, none of which were present in the entire course. Wilms's tumor must always be considered in a child and on the right side can cause obstruction of the biliary tract. It metastasizes early, and I doubt whether it can present such a picture as this in the lungs. It also metastasizes to bones, and x-ray films of the long bones were negative. Primary tumor of the liver itself seems unlikely. The liver was smooth; it showed no irregularities, and these tumors grow very rapidly and I believe would present other evidence of cancer in the patient.

Turning to the question of infection, syphilis should be considered. Against it are the negative blood Hinton reaction and the absence of changes in the long bone and of other stigmas. Brucella and fungous infections, which have been quite well ruled out by the clinicians, would not present persistent obstructive jaundice with clay-colored stools for that period. Liver abscess is, I think, a greater possibility than I originally considered. It possibly could be the source of multiple septic foci in the lung. It would be unusual for such foci to become fibrosed as these did, but this is an unusual case and we must consider every possibility. Abscess can run a fairly silent course in the liver itself and be very difficult to diagnose and sometimes, is diagnosed only by its metastatic lesions. Congenital anomalies are always a source of worry to the pediatrician. Liver cysts, cysts of the biliary ducts and stenosis of the ducts could cause half this picture but not, I believe, the complicated picture in the lung.

I come back to my original thought that, to make a diagnosis in this case, an exploratory laparotomy would probably have been necessary, and whether it was done for that reason I do not know. I should say that this child had obstructive jaundice. I do not know to what the lesions in the lungs are due. I had picked as my first choice Hodgkin's disease, but with this picture in the lungs I tend more to favor infection and should say liver abscess or localized infection in the portal fissure. I should also like to put in a guess, because of the patient's nationality, that there is a possibility of a hydatid cyst.

DR. TRACY B. MALLORY: Dr. Hampton, would you be willing to make a diagnosis?

DR. HAMPTON: No; I have not the vaguest idea. I should like to know whether an oil spray was used. It could produce that picture in the lungs.

#### CLINICAL DIAGNOSES

Biliary cirrhosis, obstructive.

Pulmonary fibrosis, chronic, nonspecific.

#### DR. MUELLER'S DIAGNOSES

Obstructive jaundice.

Liver abscess?

Hodgkin's disease?

Hydatid cyst?

#### ANATOMICAL DIAGNOSIS

Hand-Schueller-Christian syndrome, with involvement of liver, lungs, lymph nodes, bone and so forth causing interstitial emphysema (marked) and obstructive biliary cirrhosis.

#### PATHOLOGICAL DISCUSSION

DR. SIDNEY FARBER\*: The clinical diagnoses were obstructive biliary cirrhosis and chronic, non-specific pulmonary fibrosis. The exact nature of the disease was not understood by the clinicians during the life of the child, and nothing was learned from the clinical studies. As Dr. Mueller pointed out in the clinical history, the child was not malnourished and was really more unhappy than desperately ill throughout most of the course.

At autopsy, a granulomatous process that involved many parts of the body but mainly the lungs, the lymph nodes, the liver and the bone marrow, and also the kidney, uterus and tongue, was found. There was an obstructive biliary cirrhosis secondary in part to pressure on the common duct caused by enlarged lymph nodes and a mass of granulation tissue, and in part to compression of the intrahepatic bile ducts by masses of granulation tissue and granulomatous involvement of the liver parenchyma. A considerable amount of fibrous-tissue replacement of destroyed liver parenchyma was present throughout the liver. The greater amount of obstruction was caused by pressure on the common duct. The extraordinary x-ray picture of the lungs was caused by diffuse destruction of the alveolar walls and infiltration of the interstitial tissues of the lungs by the same type of granulomatous process observed in the extrahepatic lymph nodes and in the liver. Secondary to the destruction of alveolar walls, an escape of air into the interstices of the lung occurred, causing numerous small blebs and pseudocysts widely scattered throughout all lobes of both lungs. Histologically, the granulomatous process in the various parts of the body was characterized by the presence of large mononuclear cells, the cytoplasm containing large or small droplets of lipid or cellular debris, varying degrees of fibrosis and a cellular reaction composed of lymphocytes, occasional plasma cells and, in rare places where necrosis was present, polymorphonuclear

\*Assistant professor of pathology, Harvard Medical School; pathologist, Children's Hospital.

clear leukocytes. The lipid material in the large mononuclear cells stained readily by the scharlach R method, and some of the lipid was definitely doubly refractile.

The exact cause of this granulomatous process is unknown, and no further evidence of etiologic value was obtained from this post-mortem examination. Material from the lung and from the liver was injected by a variety of methods into a number of laboratory animals without the production of any lesion. Bacteriologic study of the heart's blood and tissue from the liver and spleen by aerobic, anaerobic and partial tension methods revealed no growth. The gross and histologic findings were consistent with what has been described as one variant of the Hand-Schueller-Christian disease, and what some writers have called Letterer-Siwe disease. Some patients with lung changes of the same type as those described here have had, in addition, numerous small skin lesions, which are often taken for tuberculides. Some of these patients have had destructive lesions of the skull or other parts of the skeleton. The clinical picture is often obscured by the peculiar localization of the pathologic process. In this patient, the icterus was the most significant part of the clinical picture and is explained mainly by accidental obstruction to the outflow of bile by involvement of the extrahepatic lymph nodes. Some patients have severe destruction of the petrous portion of the temporal bone. After operation, a foul purulent exudate, which may persist for weeks or months, may be found, bacterial infection being of only secondary importance.

A study of material obtained at operation and at autopsy of patients of the type under discussion and from patients with less dramatic visceral involvement, or with lesions limited apparently to the skeleton, has forced me to adopt a working hypothesis that Hand-Schueller-Christian disease, Letterer-Siwe disease and the condition that has come to be known in the last year or two as eosinophilic granuloma of bone or solitary granuloma of bone are all variants of the same disease. Certainly, it is generally recognized that the classical Hand-Schueller-Christian triad of exophthalmos, diabetes insipidus and skeletal involvement represents but one manifestation of the basic pathologic process. The disease appears to be a self-limiting granuloma. Of greatest consequence in the prognosis is the anatomic localization of the lesions.

A. PHYSICIAN: Are the lesions radiosensitive?

Dr. FARBER: Yes; we have not had very much experience, but we have learned that the bone lesions particularly are extraordinarily radiosensi-

tive. At this time, we have a patient on the wards of the Children's Hospital with liver involvement similar to that of the patient under discussion today. The liver is receiving radiation therapy.

A. PHYSICIAN: Why did they operate?

Dr. FARBER: The operation was performed in part to relieve biliary obstruction, if possible, and in part to find out the nature of the pathologic process.

## CASE 28102

### PRESENTATION OF CASE

An eleven-year-old schoolboy, apparently in good health, while playing vigorously outdoors suddenly fell unconscious, took a few breaths and died. A slight sanguineous oozing appeared from the mouth.

At birth, the patient had been delivered at term by forceps but appeared to be well. During his first year, he had presented a difficult feeding problem. At the age of two years, he had a moderately severe upper respiratory infection; at four, he had an attack of unexplained high fever for a few days culminating in a convulsion and recovery.

At five years of age, he had a severe illness that began as a bowel upset with eight to nine movements a day and a little mucus in the stools. The family physician noted for the first time slight cardiac enlargement, a rather rapid rate and a slight apical systolic murmur. There was no fever, rash, epistaxis or joint pains. In two or three days, the bowel irregularity subsided, but the heart action continued overactive without obvious cause. The patient remained quietly at home. Two weeks later, he awoke at midnight complaining of abdominal pain. He was taken to another hospital, where he was found to have a normal temperature. He was pale but not cyanotic. The respirations were rapid. There was considerable puffiness of the face and hands, and slight pitting of the lower legs. The throat was normal, and the lungs were clear. The cervical veins were swollen and pulsating, and the liver was large and very tender and extended to the umbilicus.

The heart was considerably enlarged, rapid and regular at 140. The most striking auscultatory finding was a marked gallop rhythm. There was also a soft apical systolic murmur, which later was inconstant from day to day and ultimately disappeared.

The urine was normal on several examinations. The blood showed a red-cell count of 4,700,000 with a hemoglobin of 94 per cent, and a white-cell count of 7600 with a normal differential count and smear.

An electrocardiogram showed a sinus tachycardia at 130 to 140, and moderate left-axis deviation. The T waves were low in all leads and flat in Lead 1. The P waves were rather high. The PR interval measured 0.17 second.

An x-ray film showed generalized enlargement of the heart both to the right and to the left, without characteristic shape. The transverse diameter was 11.3 cm., and the internal diameter of the chest 18.8 cm. The lungs were normal.

In the hospital, the patient was given 5 gr. of digitalis the first day, 8 gr. the second day, and 4½ gr. the third day, resulting in a striking slowing of the rate from 140 to 100 and a consequent marked improvement in the clinical picture—namely, a brisk diuresis, improvement in the quality of the heart sounds and a lessening in the intensity of the gallop to the order of a moderately loud third sound. No murmur was then audible. The peripheral edema disappeared in three or four days, and after ten days the liver receded to the costal margin. Two later x-ray films showed no significant change in heart size, and three subsequent electrocardiograms showed slightly less left-axis deviation than that on admission but otherwise remained unchanged, including the PR interval. The patient was discharged after a month of hospitalization on a daily ration of ¾ gr. of digitalis.

During the next six years, up to his sudden death, the patient remained in good health, grew normally, and was precocious mentally. His activities were essentially normal for a boy of his age. He was followed by his physicians about twice a year, and at times there was a tendency to mild tachycardia. On these occasions, the gallop rhythm reappeared but subsided with rest and slight increases in the digitalis ration. The heart remained enlarged.

Two years before death,—because of vague abdominal discomfort,—a gastrointestinal series was done in this hospital. The first portion of the duodenum showed a redundant loop crossed by a pressure defect. This deformity, which could be obliterated by manipulation, suggested to the roentgenologist an anatomic variation of the duodenum caused by an aberrant mesenteric artery.

One month before death, at the time of a routine checkup, the patient was well except for a slight respiratory infection. There was no cyanosis or clubbing and no palpable liver or spleen. There was a slight prominence of the left chest anteriorly. The cardiac apex was visible in the fifth interspace 8 cm. from the midsternal line and 2 cm. outside the midclavicular line. The action was quiet and regular at 80. There were no murmurs.

In the recumbent position, there was a slight third sound. The blood pressure was 95 systolic, 65 diastolic. Under the fluoroscope, the heart was moderately enlarged and globular in shape. The transverse diameter was 11.6 cm., and the internal diameter of the chest 19.5 cm. The lungs were normal. An electrocardiogram showed moderate to marked left-axis deviation and a PR interval of 0.20 second. The T waves in Lead 1 were inverted, and the P waves were slightly prominent. It was thought that the patient was doing well.

#### DIFFERENTIAL DIAGNOSIS

DR. PAUL D. WHITE: If this eleven-year-old boy had heart disease,—and his end sounds like a cardiac death, since most cerebral deaths are not so speedy,—the kind should be, in the order of probability, rheumatic, congenital or (quite possibly in the present case) something else. If it was either rheumatic or congenital, it was a rare case.

I cannot make much of these first events in the past history in view of what followed. Rheumatic fever generally does not take the course of a high fever culminating in a convulsion.

Almost any illness at the age of five may, however, excite acute active rheumatic heart disease, and it is possible that the sickness at that time induced the first manifestation of rheumatic or rheumatic-like heart disease with cardiac enlargement and rapid heart rate. From the intestinal trouble, I tried to work in some parasitic myocardial disease beginning during this illness, but I was unable to do so.

We do not know just how severe the abdominal pain was, except that it was severe enough to wake the patient up. One wonders if it was a complication associated with heart failure, such as liver engorgement. Pericarditis, dry or with effusion, sometimes gives rise to epigastric pain.

The patient had been flat in bed, so that this generalized edema may have been either cardiac or renal. So far as the cardiac examination is concerned, the edema might have been secondary to pericardial effusion, or it might more likely have been due to congestive heart failure. One hears a gallop rhythm frequently in constrictive pericarditis, but not in cases of acute pericarditis with effusion. The gallop rhythm is, however, much more in favor of cardiac dilatation. It can be induced by heart block alone, with long PR intervals in the electrocardiogram; the auricular contraction can then be heard.

Was the blood pressure noted at that time?

DR. EDWARD F. BLAND: It was essentially the same as it was later on.

Dr WHITE: The fact that the urine was normal on several occasions is important. We do know that at this age an acute nephritis may be associated, as Dr. Longcope and others have shown, with cardiac dilatation and often with failure that may take months to clear up.

The left-axis deviation is suggestive of something unusual at five, for even when of moderate degree it is rare at this age. The low T waves were abnormal and fit in with pericardial or myocardial disease, leaving out, of course, a state of myxedema or some other rare factor that would be very unlikely in this boy. The PR interval was rather long, but not excessively so.

Are there any x-ray films?

Dr AUDREY O HAMPTON: This film was taken six years before death. There was not much change in later examinations.

Dr WHITE: This film shows generalized enlargement of the heart. The shadow is rather globular and not diagnostic, so far as I know, of any one condition. There is, of course, so called "idiopathic cardiac hypertrophy," congenital or not, in young children, which usually does not allow survival to this age. The x-ray picture is sometimes like this one. Such cases are, however, being subdivided, and an ample cause for the hypertrophy is usually found.

Dr HAMPTON: Do you want to explain why the left main bronchus is elevated? I think it is an unusual finding for almost any type of heart disease unaccompanied by left auricular enlargement.

Dr WHITE: Enlargement of the left auricle is certainly the usual cause for such a blunt-angled bifurcation of the trachea, and yet there is no particular reason to think that the left auricle was predominantly enlarged in the present case. I do not know that I have seen it in congenital enlargement of the heart. We have, however, no oblique view to indicate the presence or absence of some enlargement of the left auricle.

The patient was able to tolerate a good deal of digitalis—most children can. The result was an excellent classic digitalis effect in the presence of normal rhythm. Undoubtedly, the digitalis was responsible for the improvement in this case. He apparently continued with digitalis throughout the rest of his life. Is that true, Dr. Bland?

Dr BLAND: That is correct.

Dr WHITE: "No murmur was then audible" This is unusual in the presence of rheumatic heart disease because even dilatation, which may persist, results in most cases in a permanent murmur or murmurs, whether the valves are deformed or not.

The patient left the hospital, to remain away for six years, in a fair state of health, except for one interval. He was, however, really a patient for those six years, not a hale and hearty, strong boy. The myocardial reserve seems to have been distinctly limited.

The aberrant mesenteric artery is very intriguing. It may be a clue to anomalies elsewhere.

The absence of cyanosis and clubbing rules out quite definitely the cyanotic type of congenital heart disease. Rarely, the tetralogy of Fallot may be associated with only slight cyanosis, but I do not believe that we can consider the usual causes for the cyanotic type of congenital heart disease in this case.

The slight prominence of the left chest anteriorly is due, I suppose, to the marked enlargement of the heart during growth, which forced the chest wall forward.

Did the fluoroscopic examination show the same findings as the earlier x-ray film?

Dr HAMPTON: Yes; both recorded a transverse diameter of about 11 cm.

Dr WHITE: The heart had not grown rapidly larger. That is, it stayed large without great change all those six years, while the body was growing. Digitalis may have helped to maintain fairly good myocardial tone and thus may have prevented greater enlargement.

This electrocardiogram might be the record of a very large heart, with hypertrophy predominantly of the left ventricle. Inversion of T waves does not necessarily mean coronary artery disease. A large left ventricle, with or without coronary disease, may produce this picture.

The death sounds like that due to coronary insufficiency. As I said in the beginning, the diagnosis must be heart disease of either rheumatic, congenital or unknown cause, and so far as I can make any positive diagnosis, it must be labeled "unknown." But I shall make an attempt. It is obvious that the patient had a large heart, particularly involving the left ventricle. There is no reason to doubt that. Whether the left auricle was large and what the other heart chambers may have shown, I do not know. I suspect that the heart was enlarged throughout, though in the left ventricle predominantly.

There was no evidence of hypertension, either systemic or pulmonary, and no evidence of valvular defect. There was myocardial disease, I think, of some sort—what kind, I cannot determine. Was it rheumatic without valvular disease? I wonder if enlarged hearts of unknown origin that we encounter in rare cases in adult life may

not be rheumatic after all, even in the absence of a positive rheumatic history or of any valvular deformity, left over from an insidious rheumatic infection involving the myocardium alone in childhood. There probably are a few of these cases, but of course we cannot prove them. And they are not common. Or this child's heart disease may have come directly from the sudden severe and obscure intestinal illness; we are, however, not acquainted with that kind of heart disease, if it exists. The patient had not had diphtheria. The electrocardiogram did not resemble such an effect. Was it toxic poisoning of unknown nature? Or was it a congenital anomaly of the blood supply? I am intrigued by that idea. This patient is rather old for it, and yet in France during the last war, in 1916, I attended the autopsy of a young soldier with an anomalous coronary circulation. His death was sudden, and we thought that it was probably due to an insufficient coronary blood supply. Consequently one can live to the age of eleven and beyond and die suddenly with an anomalous coronary blood supply. In the very striking case that we had in this hospital several years ago, the patient did not survive longer than a few months after birth. That patient had a left coronary artery that arose from the pulmonary artery and supplied the left ventricle with venous blood. We thought that, despite his age, he had angina pectoris. The electrocardiogram showed inversion of the T waves in Lead I. Later, we found the congenital anomaly and a very large heart with extensive myocardial degeneration throughout the left ventricle. Perhaps the aberrant mesenteric artery is a clue to anomalous circulation elsewhere. Could this have been von Gierke's, that is, glycogen-storage, disease? The boy was distinctly old for it, but I do not know what the oldest case on record is. The lesion might, I suppose, have been rhabdomyoma, which I know very little about except that most patients do not survive nearly to this age; most of them die within a few months after birth.

I shall guess one of the bizarre diagnoses this time; perhaps a more likely one might be rheumatic or unknown heart disease, but I favor a congenital anomaly and put my first bet on anomalous coronary blood supply and my next on von Gierke's disease; a remote possibility is some tumor such as a rhabdomyoma. My second choice as to type is rheumatic heart disease of very unusual form, and my last choice is something else that may well have been the answer that I may not even have mentioned.

DR. BLAND: I first saw this boy during his severe illness six years ago at the Children's Hospital at the request of the late Dr. Kenneth Blackfan. We were much impressed by his rapid im-

provement on digitalis; so much so that we accepted it as clinical evidence against a serious myocarditis on an infectious basis, such as rheumatic, diphtheritic or secondary to acute nephritis. Thereafter, the patient lived a fairly normal and very active life. He was closely followed because of our special interest in what we considered a most unusual form of heart disease and also because of his parents' natural apprehension about his future.

The only other comment I should like to make is that I was intrigued by Dr. Hampton's suggestion two years before the patient died that he had an aberrant mesenteric artery, because it gave some support to Dr. Blackfan's and my opinion that this was a congenital idiopathic hypertrophy of the heart. I do not know the exact explanation for the unexpected death.

DR. HOWARD B. SPRAGUE: I suppose that the patient might have had a three-chambered heart. The electrocardiogram is not like that in our series of one case, but it is a possibility.

#### CLINICAL DIAGNOSES

Congenital idiopathic hypertrophy of the heart.  
Aberrant vessel in region of duodenum.

#### DR. WHITE'S DIAGNOSES

Marked cardiac enlargement, of unknown cause.  
Congenital anomaly of the coronary circulation?  
Von Gierke's (glycogen-storage) disease??  
Rheumatic heart disease, without valvular deformity???

#### ANATOMICAL DIAGNOSIS

Hypertrophy of the heart, cause unknown.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This is the type of case in which the Pathology Department has to confess complete failure too. This patient had a very large heart—240 gm.; the estimated normal size for a boy of his age would be around 112 gm. This was twice the normal size. All the chambers of the heart took part in the dilatation and hypertrophy quite uniformly, with no evidence of preponderance in either side. Besides hypertrophy, the only definite finding was a generalized thickening of the endocardium, notable in both ventricles and even a little more marked in the left auricle. The mitral valve showed two or three spots of fibrous thickening that did not suggest rheumatic endocarditis. The chordae tendineae were not in the least thickened or short, and there was no interadherence of the leaflets. Microscopically, there was no valvulitis. We cut a great many sections of different portions of the

myocardium, and there was no fibrosis and nothing to suggest an Aschoff nodule or any arterial involvement. The coronary arteries were normal in size and location. The aberrant artery, which Dr. Hampton suggested, was found crossing the duodenum. There was an azygos lobe of the lung. Possibly, these two things could be interpreted as evidence of congenital defect, and we can call this congenital hypertrophy. I know no way of settling the matter. I can simply make a diagnosis of hypertrophy of the heart, cause unknown.

DR. WHITE: On further review of this case, I believe it unwise to label it as an example of "congenital idiopathic hypertrophy" of the heart.

There certainly was hypertrophy, with a history of congestive failure and a cardiac death, but there was no evidence of any heart trouble until the severe illness at five. To my mind, that illness in some manner, toxic or otherwise, which we do not understand, quite probably injured the heart. In view of the intestinal symptoms and fever during the severe acute illness at the age of five, when the heart trouble seemed to begin, it has been suggested that an acute trichinous invasion of the body may have set off the heart trouble.

DR. MALLORY: I think in that case we should have found encysted trichinae, since once encysted they never disappear.

## "THE AMERICAN WAY OF LIFE"

PHRASES play an important part in shaping the decisions of our national life, as they flash through the minds of men and women and strike fire from their imaginations. They help to constitute the emotional propaganda by which we form our judgments and see more clearly, or so we hope, the differences between right and wrong.

In 1917, American youth took the eastward passage to "make the world safe for democracy," and if there is too much uncertainty concerning the idealism of the movement, let the doubter see the panels painted by John Singer Sargent in the Widener Library at Cambridge. In 1942, we find ourselves having again accepted the challenge,

that in this world of chaos we may preserve "the American way of life."

What is this way of life, of which we are so proud when we find it threatened? Let us call it the opportunity that we, as a people, have seized and preserved of determining our own national destiny and of maintaining certain constitutional rights of the individual. We may not have planned our destiny well or pursued it with vigor, and we may have saddled ourselves with a government by bureaus; but we have done so of our own free will, through our elected representatives, and we still have the power to change it all, should we decide that there is a need.

In the last decade, our freedom has been jeopardized by forces that have required extraordinary opposing measures. Our economic structure has failed us to the point where we have been willing to accept an unbelievable amount of restriction in our daily activities, and in the midst of this depression, in 1931, a wave of aggression was started by totalitarian nations that we, and their other democratic neighbors, lacked the courage to stop.

When military aggression finally assumed epidemic proportions, we became aware of our own danger and began to make the sacrifices that might preserve this American way of life. Voluntarily, we have accepted military conscription; voluntarily, we are giving up our business, our professional lives and our family ties to further the great business of national defense; voluntarily, we have assumed increased taxation, burdensome debts and obedience to dictatorial powers, that, in the end, we might return to our free way of living.

We have, however, no guarantee that our liberties will be returned to us unless we ourselves retain a spirit of freedom that will require their return. Planned economies are still in the making, and it is said that federal socialization of medicine has by no means been permanently abandoned.

It will be well for us all to remember the words of Benjamin Franklin: "You have a Republic, if you can keep it."

## SANATORIUM CARE FOR RHEUMATIC CHILDREN

LAST May, the Sharon Sanatorium closed its doors to patients with tuberculosis. In the fall of 1938, a small group of children with rheumatic fever were placed in an isolated pavilion; this step was owing to the fact, now increasingly apparent, that the ultimate prognosis in this disease is determined not so much by the onset as by the insult of repeated attacks, which are so often precipitated by infections of the upper respiratory tract. The children were protected, so far as possible, from exposure to infections of the upper respiratory tract, lived on open porches, even during the winter, and were kept on more or less of a tuberculosis regime. The preliminary results of this study,\* undertaken jointly by the sanatorium and the Children's Mission to Children, were so satisfactory that the directors of the sanatorium became convinced that all the energies of the institution should be devoted to the care of rheumatic children.

In line with this change of policy, the sanatorium has been extensively rebuilt, and equipment for intensive clinical and laboratory studies has been installed. With a bed capacity of forty, divided equally between two buildings, the feature of small units has been preserved.

To provide for the sanatorium care and study of children with rheumatic infection is a new undertaking that should be followed with extreme interest by all members of the medical profession. If the results are confirmatory of those obtained with the preliminary group, it seems likely that a means will be provided for reducing not only the mortality but also the cardiac crippling that is the usual accompaniment of the disease.

## OBITUARY

### HENRY AUSTIN WOOD

1855-1942

On February 21, 1942, the long life of Henry Austin Wood, of Waltham, was closed at the age of eighty six. Born in Upton, Massachusetts, he

attended Exeter and Harvard, receiving his medical degree in 1883 and settling in Waltham in 1888. Here he practiced medicine and surgery through the professionally eventful years that followed, becoming one of those remarkable doctors whose friends are legion and whose accomplishments are almost legendary in their native heaths. Of the more than 4000 babies he delivered, probably over half were born in their homes. How many major abdominal operations he performed can hardly be estimated, but many recall protracted periods when they averaged one a day; if a day passed without one major operation, there were usually two or three of them on the day following. This volume of work may be easily surpassed in the activities of many specialists, but it must be recalled that the doctor personally attended to all the practice that generated these deliveries and operations, if one is to appreciate the immensity of Dr. Wood's daily, monthly and yearly rounds. For a quarter of a century, he served on the School Committee; for half a century on the staff of the Waltham Hospital; for many years on many local boards and committees of the city in which he worked and lived and of which he was a part. The remarkable thing, and in his later years the notorious thing, about Henry Wood was his capacity to endure this continual pressure. Younger doctors have frequently embarked on such a life, only to find themselves burned out at the end of a decade. Dr. Wood wore out scores of horses, and later when the Fords came, he wore out the Fords.

The qualities that permit a man to accomplish this are of interest. There must first be mental and physical vigor, but that is not all. Many a vigorous character has made a fair bid for similar accomplishment only to learn what every woman knows: that his wife must contribute quite as much to such a life as he himself. And other men are tripped in their headlong course by their children, or by their inability to secure the faithful ancillary services needed to keep such a practice rolling. Henry Wood was fortunate in all these ways, he attracted faithful servants, like Mary Manning and Frank Christmas; his children never tripped him up; but above all he married a discerning and unselfish person who over the years became equally well known and beloved in her adopted city—Anna Wharton Smith. She, two daughters and two sons survive him. Although it was not the sort of thing he talked about, in his declining years it was a great comfort that the younger son was carrying on his practice in the modern way.

## MEDICAL EPONYM

## MURPHY MANEUVER

On December 18, 1902, Dr. John Benjamin Murphy (1857-1916) described the following diagnostic maneuver, to which his name is frequently given, before the New York Academy of Medicine. His paper appeared in *Medical News* (82:825-833, 1903), under the title, "The Diagnosis of Gall-Stones."

... The most characteristic and constant sign of gall-bladder hypersensitiveness is the inability of the patient to take a full, deep inspiration, when the physician's fingers are hooked up deep beneath the right costal arch below the hepatic margin. The diaphragm forces the liver down until the sensitive gall-bladder reaches the examining fingers, when the inspiration suddenly ceases as though it had been shut off. I have never found this sign absent in a calculous or infectious case of gall-bladder, or duct disease.

## COMMITTEE ON MATERNAL WELFARE\*

CASE HISTORY: POST-PARTUM HEMORRHAGE  
FOLLOWED BY SEPSIS AND DEATH

A thirty-nine-year-old primipara was first seen when approximately two months pregnant and was followed for approximately every three weeks until the onset of labor. The prenatal care was excellent. The past history was not remarkable. The heart and lungs were normal, as was the blood pressure. The blood Wassermann reaction was negative. Measurements of the pelvis were said to be normal. Pregnancy was uncomplicated except for grippe at about seven months.

Labor was normal and lasted only six hours, being terminated by a simple forceps delivery. Previous to delivery, the patient had been given two injections of pituitary extract, each consisting of 5 minims. She sustained a first-degree tear of the perineum. There was difficulty in the delivery of the placenta, which was expelled only after the greatest effort. The central part of the placenta was described as pale and had apparently been firmly

attached to the uterus. There was no mention of unusual bleeding until two hours after the placenta had been delivered. At this time, the patient was said to have been flowing very freely. Ice, ergot, pituitary extract and morphine were administered. The patient suffered another severe hemorrhage the following morning, and she was given 500 cc. of citrated blood. On the fourth day, a septic temperature developed. Two more transfusions were administered. Death from sepsis resulted on the seventh day. No autopsy was performed.

*Comment.* The use of pituitary extract in such large doses cannot be condoned. Presumably, although the record does not state this, the administration was delayed until full dilatation. The intelligent use of pituitary extract in minim doses after full dilatation when there is no disproportion is good obstetrics and frequently results in normal delivery. The record makes no note of any difficulty in the delivery, nor did the patient suffer any severe lacerations. Episiotomy was not performed. Most obstetricians prefer episiotomy, with its resultant clean wound, to the ragged laceration that the perineum so often sustains. The description of the placenta leads one to think that some placental tissue may have remained because of a minor degree of adherent placenta, or possibly that a true area of placenta accreta existed. The hemorrhage following so long after delivery, with the description of the placenta, confirms this supposition, and the fact that no subsequent hemorrhage is recorded in no way contradicts it. There is no mention in the record that the uterus was invaded after delivery. A hemorrhage such as that described usually stimulates intrauterine investigation. If the uterus had been invaded and an accreta diagnosed, hysterectomy after transfusion would have been the logical course. If a piece of adherent placenta had been found as the cause of this post-partum hemorrhage, it might have been removed manually. At any rate, in the face of such hemorrhage, it would have been wise to have packed the uterus and, if hemorrhage continued, to consider the advisability of hysterectomy. According to the record, however, no subsequent hemorrhage developed, but sepsis did follow. It is quite possible, in spite of the lack of positive evidence, that the uterus in some way was invaded at the time of the severe hemorrhage. If this was so, the following sepsis may have had its beginning in this manipulation. This death occurred before the era of chemotherapy.

\*A series of selected case histories will be published weekly. Comments and questions by subscribers are solicited and will be answered by members of the committee. Letters should be addressed to the secretary, Dr. Raymond S. Titus, 230 Dartmouth Street, Boston.

## CONGRESS ON MEDICAL EDUCATION AND LICENSURE

The thirty eighth Annual Congress on Medical Education and Licensure held recently in Chicago proved so interesting that as delegate from the Massachusetts Medical Society, I am presenting certain impressions of the meeting while the various happenings are still fresh in my mind.

On Saturday afternoon, February 14, I attended a long meeting of the Association of American Medical Colleges. Here for more than five hours, the matter of the accelerated program of medical education was discussed. The upshot of the discussion led to several resolutions which were passed by that body. Among the most significant were the following:

Approval by the association of the accelerated program as an emergency measure.

Minimum standards for an approved course to include four terms of not less than thirty two weeks each, and no student to graduate sooner than thirty six months after his registration as a first year medical student.

Standards of eligibility to an approved school not to be lowered.

The council of the association was ordered to negotiate with the proper governmental agency for the establishment of a student loan or scholarship fund not to exceed \$3,500,000 a year, loans or scholarships from such a fund to be awarded on the recommendation of their deans to students needing financial assistance to carry out the accelerated program.

The association did not approve at the present time of asking federal grants to help in the financing of medical education, such aid as was to be sought was clearly in order to help needy students rather than the financial state of any medical school.

Internships were not to be regarded as acceptable when they were of less than twelve months' duration.

No school was to feel any sense of compulsion to attempt an accelerated program. Unless such a program could be carried out effectively by any school without lowering the quality of the medical education offered, it should not be initiated.

Before these resolutions were passed, Dr. Walter Biering, of Iowa reported that sixty three schools had already made plans to proceed on the accelerated program. He gave a careful analysis of individual state board rulings, which showed the difficulties that certain states will have in modifying their medical registration laws to be compatible with an accelerated program of medical education.

Major Sam F. Seeley, of Washington, D. C., outlined the plans of the Procurement and Assignment Service. A complete account of this has been printed in the February 21 issue of the *Journal of the American Medical Association*, so that I shall not attempt to describe it here. Major Seeley, however, emphasized that the Procurement and Assignment Service will do all in its power to protect hospitals, medical schools and communities from medical

deprivation. It is hoped that enough volunteers who are not essential doctors will be found to yield an adequate supply of medical officers for the needs of the armed forces. He described the methods to be pursued for grading essential doctors and for the deferment from active service of commissioned officers who at present are doing work essential to civilian needs. The success of the plan will hinge on the readiness of all physicians to supply data by filling out in detail the form that will soon be sent them and on their unselfishness in being ready to undertake any type of work assigned them.

Dr. Willard C. Rappleye of New York City, added significantly to the afternoon's discussion. He traced the development of the accelerated plan and pointed out that it had come into being largely because the Selective Service System realized the urgent need of physicians for military and civilian use and failed to see the necessity in times like these of the long vacation for medical students hitherto in vogue. On the other hand he reiterated that although the emergency must be met standards of medical education must not be lowered.

As a concluding item on the program Dr. Fred Zippfe of Chicago, called attention to the present shortage of microscopes for the use of medical students. He suggested that a survey of the supply of microscopes be made by each school and that microscope loan pools be established in different schools through their alumni associations. Alumni owning microscopes and not using them regularly could do a great service in lending their instruments to students, because new ones are almost unattainable. By such means an adequate number of microscopes, properly conditioned could be made available to students at relatively little expense. He also pointed out that a shortage of blood counting equipment and blood pressure machines may develop.

On Sunday, February 15, I attended the meeting of the Council on Medical Education and Hospitals of the American Medical Association. The council supported the attitude of the Association of Medical Colleges toward the accelerated program of medical education, emphasizing, too, that the decision of a medical school to initiate such a program was not compulsory and should be reached only after a comprehensive survey of its own ability to speed up its program of education without deterioration of the quality of its medical instruction.

On Sunday evening, I attended a joint meeting of the Council on Medical Education and Hospitals and the Advisory Board of Medical Specialties. This provoked interesting points of view. It seemed fair to presume that specialists would be of use to the armed forces and would continue to be of use to the civilian population. Therefore new specialists should be developed to meet these needs, and the idea of continuing training for properly equipped young physicians should not be abandoned. Various suggestions concerning how this might be best accomplished were debated.

The Annual Congress on Medical Education and Licensure was held during the following Monday and Tuesday, February 16 and 17. All the papers that I heard were interesting, although I was especially impressed with the one on Monday morning by Professor William B. Munro, of Pasadena, California. His title was, "The War, the Colleges and Federal Aid." His viewpoint seemed to be that we had already developed in the United States, through our plan of wide collegiate education, a good many college graduates who by no means were well educated. If governmental funds were to be made readily available to colleges, he feared that emphasis thereby might be laid on the quantity of students accepted rather

than on the quality of the education that they received, and this to him seemed unwise. He stated that scholarships with which to assist needy students, should federal aid become available for this purpose, were better than loan funds because they could more easily be awarded on the basis of scholastic aptitude and need rather than on need alone. He concluded by saying that, in his opinion, endowed universities should do all in their power to maintain their independence. Evidently, he feared that too much in the way of governmental subsidy of education might lead to restriction rather than to liberality in thought and study.

Monday afternoon was devoted to a discussion of war problems. Colonel George F. Lull spoke for the Army, Surgeon General Ross T. McIntire for the Navy, Surgeon General Parran for the Public Health Service, Colonel Leonard G. Rowntree for the Selective Service System, and Dr. Irvin Abell for the Committee on Medical Preparedness of the American Medical Association.

The need for doctors was emphasized again. The type of training that would develop most desirable officers for the Army and Navy was described. What the Selective Service System has already accomplished was brought out very graphically. And, finally, that all doctors will be useful to the country in some manner was made very plain.

Dr. Harold S. Diehl, of Minneapolis, concluded the session with an interesting paper on "The Role of Medical Schools in the War." It seemed clear to him that, of necessity, medical students must play an increasingly significant part in the country's history. Already certain features of military medicine have become of great importance to the country's needs, and he suggested that medical educators might well begin to point their teaching in the direction of giving medical students a better knowledge than heretofore of these new matters. He suggested, for example, that "first aid" should be taught to first-year medical students. The emergency care of wounds and minor sepsis deserves more systematic attention than this topic often receives in the normal peacetime curriculum. Psychiatry is rapidly becoming of noteworthy significance. Public health, tropical medicine, dermatology and venereal prophylaxis are general subjects that Army officers report as being inadequately covered in the undergraduate courses, as evidenced by lack of knowledge in these matters on the part of newly inducted officers. Finally, aviation medicine should be taught more emphatically, especially from the viewpoint of its physiologic aspects. Aviation medicine offers an important field of endeavor to competent young men with sufficient basic knowledge and training to enter it successfully.

On Monday evening, I attended the dinner of the Federation of State Medical Boards. This ended in a prolonged discussion of the accelerated program, entered into by state health officers from all over the country. The conflict of certain medical registration acts toward such a plan was again described. Finally, the federation expressed itself as being in sympathy with the move toward an accelerated program of medical education, regarding this, however, as a war emergency measure rather than as a permanent change in policy. It was stated that, when necessary, state laws on medical registration should be so modified as to make acceleration permissible during the period of emergency.

The program on Tuesday dealt less with matters pertaining to war medicine.

The Congress on the whole was the most significant one that I have attended. I came home feeling that the medical profession is playing a major part in national de-

fense, and is solving the many problems with which the country is now faced in a manner both creditable and intelligent.

REGINALD FITZ

### "THE INNER WORLD OF THE CHILD"\*

The child's inner world is full of color and feeling. It is simpler than the world we know and sometimes happier. The child has little information, but a great deal of curiosity. This curiosity is usually an expression of his need for learning. Sometimes, it can be an expression of the child's anxiety or his fears.

The child imitates and acquires. He learns by doing and imagining. He wants to love and be loved. He is only vaguely aware of what adults see in the world around them. He knows the difference between pain and pleasure, having and not having, coming and going away, death, to him, means little more than going away.

The child has many needs of which he may not be aware, and often he finds it hard to make his wishes clear. Thus, he must depend on the adults around him to understand and take care of his needs in a healthy way.

Next to himself, in the inner world of the child, the mother and father—or their substitutes—are most important. They are king and queen of the child's court, the mountains on both sides of his valley. In the simplicity of his inner world, the parents loom like giants or heroes toward whom he has affectionate and anxious feelings. Parents often forget this; some never know it.

Between the external situation of his life and his internal emotions, the child has to strike some sort of balance or make some sort of adjustment. But there is always a gap between what he wishes and what he gets from reality, and that gap, or deficit, is what fantasy fulfills. Whether it is made up in play, by story-telling, in little private dramas or in daydreaming, his fantasy life is always significant. It shows the direction in which the wishes go, as well as the failure of environment to provide what the child wants. The fantasies of a child are naturally fantastic. When they become real, they may be the accomplishments of the world. Fantasies and only fantasies explain the pyramids of Egypt, or an empire. Sometimes, the child's dream is more important to him than reality, or anything else in the world, and far more beautiful. It is natural for him to have daydreams. Don't laugh at him, or you may kill the goose that lays the golden egg. At some time or other in childhood, every girl is Cinderella or Snow White, and every boy is George Washington or the Dutch lad who held his finger in the hole in the dike.

The child does not understand the outer world as we understand it, but he understands it by what is called *intuition*, especially how it feels toward him; for example, it is said that children and dogs sense instantly how strangers feel toward them. Usually, children know without being told how those around them feel. Children are not so unaware of things as they may appear to be; as Wordsworth said, they are "not in entire forgetfulness, and not in utter nakedness."

If there is hostility or financial tension in a home, children sooner or later are aware of it. If there is pain or suffering or insecurity around them, they know about it. If there is conflict between parents, children sense it; they do not need to be told. They soon learn to adjust them-

\*A "Green Lights to Health" broadcast given through Station WAAB by Dr. Merrill Moore on Saturday, December 20, and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

Let it or take advantage of it. On this account and the good of the child, if for no other reason parents would present a united front to their children, and when it is possible, should keep in fair agreement. Otherwise, the child quickly learns to play one off against the other, and from the point of view of discipline such a child sits down between two chairs." That is how he learns to feel conflict in himself, and how to be undisciplined and disorganized, for a child takes on a part of the personality of each parent.

If a parent is disturbed or hurt, this can be reflected in the child's conduct, play or schoolwork. One teacher who has what I call emotional intelligence said to me recently, "When a child we know to be bright begins to do poor work, we always look to see what is wrong at home. This point has been emphasized by Dr. Douglas A. Thom, Director of the Habit Clinic for Child Guidance in Boston. Dr. Arlie V. Bock, who has made similar observations in his study of normal college students at Harvard, believes that when students who have good minds fail to do good work, it is usually the reflection of some inner emotional problem or a disturbance at home."

The child is aware of his own body, which is very important to him. He begins early to understand what he is told about it. He remembers part of what he is told, and sometimes he can use that information with a kind of inborn intelligence.

Children recognize and appreciate the truth. They may ask either direct or indirect questions. It is essential for the parent to be aware of the possibilities of indirect questions, and to try to satisfy the child's curiosity, but the parent should not be overconscientious and answer questions that have not yet arisen in the child's mind. This confuses and overstimulates the child. A single question may need to be answered many times, since the child's growing understanding gradually takes in different phases of the answer.

Very close to the heart of a child is his awareness of his own sex. This should be treated with conscious respect. Adults can do a great deal to disturb the emotional development of some children, through misinformation or teasing. I know one person whose usual approach to a child (if it is a boy) is to say, "Oh! what a pretty little girl!" This always gets a rise out of the child, which the adult enjoys. But sometimes the child is mortified or enraged, and this may be only fuel to the flames of vanity in a person who likes to show off or be cruel.

It is normal for children to exhibit and, in childish ways, to be unkind. But as they grow up and learn other pleasures, normal people tend to give up childish behavior. Small boys are naturally rough and aggressive, but modern nursery schools are doing a great deal to show parents how to deal with these impulses in a constructive way. Well-run nursery schools have much to offer parents as well as children, and a tactful, intelligent kindergarten teacher can do much to help the child bridge the gap between home and primary school, and thus make happy adjustments to the demands of a group of children of his own size and age and general capacity.

Next to kindness, the child's greatest need is to be told the truth—to be given information he can use—again and again. This is how the child gains intellectual security. After the truth, the child needs fairness in all dealings with him. Fair treatment means more to the child than many people realize. Some of the most violent deeds in the world have been done as the result of a hurt or defeated sense of fair play. Children understand that. A woman told me once that Lincoln's Gettysburg address

always brought tears to her eyes when she heard it. I asked her why. She said, "Because it makes me feel he was so kind and so fair!"

To boil it down to a few words, then, What does a child need to make his inner world well organized? His efforts well directed, his expenditure of energy balanced and his whole personality free from conflict and unnecessary suffering? What can he acquire from the world around him, including his parents? Ideally, a good constitution and healthful living conditions, an opportunity to play and to learn to work. Practically, the child needs what the adult needs only more of it. There is no limit to the amount of affection a child can take, short of spoiling him. He needs to be praised, guided and reassured. Parents should try to instill self-reliance and not teach children to fear, as some silly people do. A child needs science, in its elements and art. Show a child a miner's sea-shell, a fossil, an insect or an animal. Notice the pleasure it gives him. Or show him a picture, a statue, a poem or a place, and tell him the story of it. He will enjoy that and learn from it. A child's attention is easy to gain but not so easy to hold for his span of attention is short. However, all the time you are speaking to a child his brain is recording what you say, and his spirit is being fed by it.

All the time you are with a child you are giving him facts, experiences, good or bad suggestion, and beautiful or ugly images. It is out of this material that he builds the inner world of his mind. In this inner world, his self (or ego) lives. It is a self that the world may later come to know happily or unhappily. It is this self that has to deal with his emotions and his conscience and with the outside world. For a child to grow and function best and cope with what he has to meet to grow up and go through life, he needs health, protection, security, affection, guidance and discipline, a chance to develop independence and real opportunities to be happy and useful.

## DEATH

GOODWIN—HAROLD C. GOODWIN, M.D., of Springfield, died March 1. He was in his sixty-fourth year.

Born in Peabody, Dr. Goodwin received his degree from Dartmouth Medical School in 1900. He was division examiner of prisoners for the Commonwealth of Massachusetts and was a member of the staffs of the Mercy and the Wesson Memorial hospitals and of the Mary Lane Hospital in Ware. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow and two sons.

## MISCELLANY

### RESULTS OF THORACOPLASTY

The number of persons whose pulmonary tuberculosis has been arrested through the aid of thoracoplasty is steadily increasing. They will require medical surveillance for the rest of their lives. They are not immune to other diseases. Since any doctor may be called on for advice, it is desirable that all members of the profession be familiar with the changes in the thorax that are brought about by thoracoplasty. An abstract of a recent discussion (Overholt, R. N. Permanent collapse therapy in pulmonary tuberculosis. *JAMA* 117:1681-1697, 1941) follows.

In advanced tuberculous disease, tissue destruction and cavity formation have taken place, the elasticity of adja-

cent segments of the lungs is frequently decreased, and the volume of the healthy lung is so reduced that it is incapable of filling the unyielding thoracic space. How can healing take place under such conditions?

Pulmonary cavities must be closed and must remain closed. Fibrous tissue must not tear under the strain of ordinary thoracic movement, to ensure against reactivation or hemorrhage. The scar must be solid, but at the same time its contraction should not pull thoracic viscera out of position to the extent that cardiorespiratory function is impaired. Certain patients are fortunate enough to make these adjustments spontaneously, arrest the process, and enjoy moderate activity without reactivation. For a second group, the problem has been solved by an adequate pneumothorax (or other temporary measure), which is maintained indefinitely with safety. There is a third group to which thoracoplasty is not applicable; patients who have disease so extensive and so distributed as to make it technically impossible to bring it wholly under control by any single method or combination of methods must be excluded from this discussion.

A significant proportion of tuberculous patients do not fall into the foregoing categories. The health of patients in this fourth group can be restored with surgical help. They are those patients who suffer from advanced disease with irreparable pulmonary damage.

A discrepancy exists between the volume of healthy lung and the volume of the thorax. Temporary measures have failed or present no reasonable chance of being effective. They have an equivalent of two healthy pulmonary lobes, the two on one side or one on each side. Preferably, the disease is stable. The thoracic cage can be refashioned and the diseased lung released from its anchorages. The permanently altered position of the chest wall provides a permanent collapse.

Modern thoracoplasty accomplishes the following: fibrous tissue is released, permitting cavity closure; pulmonary tissue, which has been partially damaged but not totally destroyed and whose elasticity has been impaired by fibrosis, is relaxed; limitation of motion is imposed on the diseased lung; the collapse of the lung can be made highly selective, with conservation of healthy portions of the lungs; and disturbances due to distortion of the thoracic viscera, such as upward displacement of the lower lobe and lateral displacement of the heart and great vessels, are corrected.

All these readjustments are common accomplishments of a free pleura pneumothorax and thoracoplasty. In addition to these considerations, there are added benefits that are unique for thoracoplasty: thoracoplasty adjusts the thoracic volume so that it comes to equal the volume of the healthy lung—in other words, the functionless portion of the lung is placed under permanent control; the risk of tuberculous or mixed empyema developing in an artificially maintained air space is eliminated; and the risk of spontaneous pneumothorax on the side of treatment is greatly lessened.

The ultimate fate of patients treated by thoracoplasty cannot be determined until more time has elapsed. However, a preliminary study made of patients treated successfully by thoracoplasty and discharged with the consent of their medical advisers is most encouraging. Of 107 patients discharged five or more years, 101 are living, 3 died of tuberculosis and 3 died of other causes. Of 315 patients discharged under five years, 308 are living, 1 died of tuberculosis, and 6 died of other causes.

Although exactly comparable end results are impossible to find, it is fair to assume that the severity and extent of the process from which the groups under discussion suffered were more threatening than those of the aver-

age patient undergoing sanatorium treatment. Yet they seem to fare better, for a study of 6906 patients discharged alive from various sanatoriums in this country revealed that only 60 per cent of those discharged with consent were living after a period of five years.

In support of the belief that permanent collapse increases the chances for lasting results, the author quotes Roberts from the *Brompton Hospital Reports* (1936) as follows: "It is shown that the chance of surviving five years in B 3 cases [not defined in the article] treated without collapse was 23.7%; with pneumothorax, 55.3%; and with thoracoplasty, 66.6%. Thus, the expectation of living five years is approximately three times as great in cases submitted to thoracoplasty as in the average B 3 case."

A questionnaire sent to patients treated by thoracoplasty and discharged with consent brought 293 replies. The great majority considered themselves well and were glad they had had a thoracoplasty; 83 per cent were able to work; and 70 per cent declared they had no limitation of arm or shoulder motion. Many letters that accompanied the questionnaire replies stated that the scar and changes in contour of the chest constituted a small price to pay for restoration of health, and many stated that their only regret was that the operation had not been performed sooner.

Several refinements of thoracoplasty have been made since de Cernville performed the first thoracoplasty in 1885. These include lung palpation at operation, specific mobilization and the liberation of anchoring structures over areas of disease, preservation of periosteal elements and subtotal scapulectomy to minimize deformity in partial thoracoplasty.—Reprinted from *Tuberculosis Abstracts*, February, 1942.

## CORRESPONDENCE

### STUDY AND TREATMENT OF CONTAMINATED WOUNDS AND BURNS

*To the Editor:* The Surgical Service of the Massachusetts General Hospital has entered into a contract with the Office of Scientific Research and Development of the United States Government for the study of contaminated accidental wounds and burns and their treatment. The value of the study will be increased if a large number of compound fractures, severe lacerations and extensive burns can be obtained. Toward this end the hospital wishes to notify physicians that facilities will be made available for the transportation and admission of suitable cases on the recommendation of the attendant physician. Ambulance service and admission may be secured through the Admitting Office of the Hospital (CAPitol 4300).

## BOOK REVIEW

*A Manual of Bandaging, Splinting and Strapping.* By Augustus Thorndike, Jr., M.D. Philadelphia: Lea and Febiger, 1941. 144 pages, with 117 engravings. \$1.50.

This is a very handy reference work for those who wish to apply a neat dressing or bandage of any kind. Most of the book is devoted to well-drawn illustrations, which require very little explaining. It should prove popular at this time to the hundreds of people who have suddenly developed an active interest in first aid.

## CURARE TREATMENT OF SPASTIC CHILDREN\*

### Preliminary Report

ERIC DENHOFF, M.D.,† AND CHARLES BRADLEY, M.D.‡

EAST PROVIDENCE, RHODE ISLAND

FOR centuries, curare has been known as a drug that paralyzes voluntary muscle. For many years, clinicians have recognized that spasticity in the form of persistent involuntary contraction of the voluntary muscles is often one of the most serious obstacles to effective treatment of children with cerebral palsy. Only recently has it been suggested that the paralytic effect of curare might be used to reduce this spasticity and thus expedite the rehabilitation of these patients. The present study was undertaken with the hope of increasing knowledge concerning the clinical safety and efficiency of curare as a therapeutic weapon against spasticity and to establish some standards and criteria for its use.

Curare is made up of a mixture of liquid extracts of several plants of the Strychnos group, whose most striking pharmacologic action is paralysis of skeletal muscle. It was first taken to Europe by Sir Walter Raleigh in the latter part of the sixteenth century after he had observed that the South American Indians were using it as an arrow poison. When thus used, it killed its victim by causing respiratory paralysis. The physiologic action of curare was not thoroughly investigated, however, until the middle of the nineteenth century, when Bernard<sup>1</sup> reported that its site of paralytic action on skeletal muscle was at the myoneuronal junction. The drug was subsequently employed at intervals in Europe in the clinical treatment of spasmodic disorders, such as tetanus and epilepsy. However, it could be obtained only from the South American Indians of the Amazon region. The supply was uncertain, the concentration was variable, and the stability of the drug unknown. For these reasons and since overdosage killed the patient by respiratory paralysis, the extensive clinical application of curare was imprac-

tical until recently. In 1938, for the first time, large amounts of the drug of known origin were brought back to the civilized world by Gill,<sup>2</sup> and since that time considerable progress has been made in preparing and reliably standardizing curare for clinical use.

In a recent review, Goodman and Gilman<sup>3</sup> summarize the composition and action of curare somewhat as follows. One obtains it by brewing the stems, roots, bark and leaves of several varieties of Strychnos and boiling down the extract to a thick resinous mass. This is soluble in water and in alcohol. The active principles are alkaloids whose chemical structure and chemical basis of action are still unknown. The pharmacologic effect of curare is that of an autonomic blocking agent. It acts mainly on skeletal muscle and to a lesser degree on autonomic ganglions, preventing the response of these cells to nerve impulses or injected acetylcholine. Curare apparently acts directly on the cells themselves at the myoneuronal junction. It does not impair the formation of acetylcholine but prevents that substance from eliciting its usual response. Curare does not inhibit the response of the muscle cells to other forms of stimuli, since curarized skeletal muscle still responds to direct electrical stimulation.

In curare poisoning, the curarized muscle first shows fatigue and weakness, later flaccidity and finally complete paralysis. The muscles of the digits, the eyes and the ears are first affected, then those of the limbs, trunk and neck, and finally, after adequate doses, the muscles of respiration. Death is due to respiratory paralysis. The action of curare is supposedly transient, and life may be preserved if artificial respiration is employed until the drug is destroyed or excreted. It is supposedly partly destroyed in the liver and partly excreted through the kidneys. The drug is entirely ineffectual when given by mouth, unless absorbed through a wound or extensive ulcera-

tion in the gastrointestinal tract. Theoretically, physostigmine and Prostigmine are pharmacologic antagonists to curare in their stimulatory phase of action on ganglions and skeletal muscle.

Interest was first aroused in the possible therapeutic value of curare in neurologic disorders, such as cerebral palsy, by Bremer's<sup>4</sup> report in 1929 that small doses, insufficient to paralyze the intact skeletal musculature completely or to embarrass respiration, selectively relaxed the muscle spasm in animals with decerebrate rigidity. Hartridge and West,<sup>5</sup> in 1931, reported that curare removed the violent spasms of tetany in doses that failed to paralyze the animal. This indicated that doses sufficiently small to be safe in human beings might be of benefit in relaxing muscles that are pathologically hypertonic. West<sup>6</sup> suggested the term "lissive" for this action, which relaxes but does not paralyze. Burman<sup>7</sup> noted that curare was beneficial in certain spastic and dystonic states in human beings and later reported a girl with spastic paraplegia as one in a series of patients suffering from neurologic disorders whose muscular rigidity was diminished following 20-mg. doses of curare.<sup>8</sup> Burman made the interesting observation that in some patients the beneficial effects of the drug lasted for three or four days following injection. Pusitz et al.<sup>9</sup> reported using curare on 7 children with cerebral palsy, but did not specify the size or frequency of dosage in all cases. They described "weakness and lassitude" lasting well into the day following an injection of 45 mg., and noted that doses definitely smaller than those sufficient to produce paralysis relaxed hypertonicity in spastic muscles. Bennett<sup>10</sup> reported the treatment of 12 patients suffering from severe spastic paralysis with curare in doses of 10 mg. per 20 pounds of body weight injected every second day over periods of months. Improvement in terms of transiently reduced spasticity during the period of injection was noted in several cases. There was no permanent relaxation as the result of treatment. Bennett suggested that the use of curare might facilitate muscle training and physiotherapy in such cases.

Apparently, not more than 20 cases of cerebral palsy treated with curare have been reported in the literature, and in few of them are specific dosage and response discussed in any detail.

#### MATERIALS AND METHODS

The present study is based on observations of the effects of curare administered in various doses by each of several routes at various intervals to 6 children with cerebral palsy. The patients ranged in age from seven to twelve years; they were all

of normal or superior intelligence, and spasticity was a prominent symptom in all. These children were resident patients at the Emma Pendleton Bradley Home during the four-month period covered by these observations. They had been under the supervision of an experienced physiotherapist and of graduate nurses of the permanent hospital staff for several months prior to this study. While the patients were receiving curare daily, detailed records of their activities and reactions were kept by this staff, and daily observations and examinations were made by one of us (E.D.). Throughout the period of study, except for the time spent in administering the drug and in carrying out specific tests, each child continued his usual daily activities of physiotherapy, academic schooling, occupational therapy and free play, individually and in the group.

*Specific medication.* The curare used in this study is known commercially as Intocostin.\* This is a physiologically standardized extract of curare secured from the Amazon forests. It is supplied in sterile ampules, 1 cc. of the yellow, watery solution containing the equivalent of 20 mg. of a standard curare.

*Route of administration.* In an attempt to ascertain the most favorable route of administration, doses were given to each of 2 children on different occasions by subcutaneous, intravenous and intramuscular injection. As discussed below, the intramuscular route proved the most satisfactory, and subsequent determinations of optimum dosage and intervals of administration were made on the basis of this method.

*Dosage.* The optimum dosage for each child was determined by systematic noting of the clinical response to gradually increasing amounts given intramuscularly on separate days. The first dose was 5 mg., and on subsequent days the individual dose was increased approximately 5 mg. each time until mild paralytic symptoms of overdosage appeared. A maintenance dose was then established slightly (4 to 8 mg.) below this level. The constancy of response of each child to his optimum and paralytic doses was striking, and suggested a gratifying stability of potency of the curare preparation.

Once an optimum dose for a child was determined, the therapeutic effect of repeating this dose at intervals of one, two, three and four days or even longer was noted.

*Control periods.* To eliminate any confusion resulting from the possible beneficial effects of curare injection through suggestion or other psychologic

\*Supplied through the courtesy of E. R. Squibb and Sons, New York City.

means, the response of each patient to intramuscular injection of sterile saline solution was noted. This injection was given under precisely the same conditions as those of curare administration.

After each child had been on his maintenance dose for some time, a period of several days to several weeks without medication was arranged, and the response noted.

*Tests of response to curare.* Apart from the general observations by hospital staff of each child's response to medication, a number of standard clinical and laboratory tests were employed in an effort to record objectively any evidence of improvement or untoward reactions.

Three standard motor-performance tests used in the psychologic laboratory were employed in evaluating the response to varying amounts of the drug. The pin board, peg ball and tracing board were used, as described by Garrett and Schneek.<sup>11</sup>

Electrocardiograms, observations of the pulse and respiratory rates, blood pressures, body temperatures, urinalyses and determination of renal function and various blood chemical levels were studied in all 6 children at various points during treatment. Electroencephalograms, taken immediately before and soon after an injection of curare, were performed on 1 patient.

*Curare combined with other drugs.* Observations were made of the effect of curare on each child's response to amphetamine (Benzedrine) sulfate as an extension of studies previously undertaken at the Bradley Home.<sup>12, 13</sup> Daily morning oral doses of 10 and 20 mg. of amphetamine sulfate\* were administered for several days during the time that each patient was receiving his maintenance dose of curare at optimum intervals, and changes in his reactions were noted.

## RESULTS

### Clinical Studies

*Dosage.* Following the injection of small and therapeutically ineffective doses of curare, the children within a few minutes complained of being dizzy and feeling "heavy." They often rubbed their eyes at this time, but these symptoms seldom lasted more than ten minutes. On clinical examination, the muscles of the hands appeared less spastic and more relaxed than usual for periods up to an entire day following these small doses. There was no other persistent or delayed response to these amounts, however.

Following what was later determined to be the optimum individual maintenance doses of curare, a more definite and persistent response was noted.

In about fifteen minutes, the children felt "sleepy" for a brief period. Shortly thereafter, they were noted to be somewhat unsteady, with masked facies and some drooping of the eyelids. Double vision was a frequent complaint at this point, but these symptoms disappeared in about half an hour. For approximately two days after the injection, the patients stated that they felt "light" and "happy." For approximately four days, the muscles of the feet and legs, fingers, hands, arms and trunk were relaxed. The reduction of spasticity was more marked in the lower than in the upper extremities. During this period of relaxation, speech was clearer and motor performance definitely smoother than usual. Any drooling that had formerly been present was diminished.

About fifteen minutes after the administration of large, paralytic doses of curare, the children became pale and mentally confused. This lasted between thirty and forty minutes, and was accompanied by definite drooping of the eyelids and relaxation of the neck muscles, which allowed the head to drop forward. There was excessive perspiration, and slow shallow respirations. The symptoms, which were alarming and suggested shock, disappeared without special treatment in about forty minutes, for the following twelve hours, however, the body musculature was definitely hypotonic, and the children were listless. Lethargy sufficient to interfere with any treatment program persisted for about twenty-four hours. Relaxation of spastic muscles, however, was noted for five or six days. During the latter part of this period, following recovery from a state of sluggish hypotonia, relaxation and motor performance during periods of muscle training were better than when the drug was not given.

The responses of patients to curare can be classified as immediate (those coming on within fifteen minutes to half an hour after injection) and delayed (those first appearing about a day after the drug is given). These effects, as noted on the 6 children under investigation, are presented in Table 1.

*Optimum route of injection.* The general response of all children to various doses of curare as just described varied somewhat, depending on the route of administration. When curare was given intravenously, muscular relaxation appeared almost immediately, however, paralytic symptoms, with evidence of respiratory embarrassment, also appeared often and immediately and to an alarming degree. For this reason, the intravenous route was abandoned, since extreme paralysis was hardly an aid to treatment.

\*Amphetamine (Benzedrine) sulfate was supplied through the courtesy of S. H. Kline and French Laboratories, Philadelphia.

Subcutaneous injection of the drug in doses found efficacious by other routes gave no consistent or desirable response. Consequently, this method was discontinued.

Intramuscular injection, usually into the buttocks, gave a good physiologic response, without

ing accentuation of response to the repeated injection of the same amounts of curare, although the difference between optimum maintenance and paralytic doses was not great. This suggests that individual patients respond in a constant manner to identical dosage, and that the preparation of curare

TABLE 1. Summary of Physiologic Responses to Curare in Various Doses.

SIZE OF DOSE	IMMEDIATE RESPONSE			DELAYED RESPONSE		
	SYMPTOMS	SIGNS	THERAPEUTIC EFFECT	SYMPTOMS	SIGNS	THERAPEUTIC EFFECT
Minimal (sub maintenance)	Dizziness and heaviness (transient)	"Sleepy" eyes for 10 minutes	Relaxed muscles of hands for 24 hours	None	None	None
Optimum (maintenance)	Sleepiness for 10 minutes	Unsteadiness, diplopia, lid lag and masked facies for 30 minutes	Relaxed muscles in fingers, hands, arms, trunk and lower extremities for 4 days	Feeling of lightness and happiness for 2 days	Diminished drooling for 4 days	Good muscular relaxation, efficient performance and clearer speech for 4 days
Maximal (paralytic)	Mental confusion for 40 minutes	Neck drop, pallor, excessive perspiration and diminished respiration for 30 minutes	Hypotonicity for 24 hours	Lethargy for 24 hours		Good relaxation and efficient performance for 5 or 6 days

the immediate, alarming symptoms of paralysis that had followed intravenous administration. The intramuscular route was therefore selected for therapeutic use, and the remaining conclusions are reported on this basis.

*Optimum dosage.* As shown in Table 2, the optimum maintenance dose varied considerably from one child to another. In general, the patient with the most extensive and intense spasticity not only tolerated but profited from the largest doses as de-

used is accurately standardized and remarkably stable.

To eliminate any confusion concerning the role of suggestion in producing the clinical results noted, the patients were at various points in the study given intramuscular injections of sterile saline solution, or no injections at all. In each case, complete absence of the curare response was noted.

*Optimum intervals between injections.* Once the optimum maintenance dose of curare was established for each child, the effect of repeating this dose at varying intervals was studied. The most satisfactory therapeutic results appeared when curare was administered at four-day intervals. Under this regime, there was some initial lethargy, which wore off promptly and allowed two or three days of relaxation without loss of energy. During this period, a training program could be efficiently carried out for each child. At intervals shorter than four days, the patients under treatment were more or less constantly drowsy, sluggish and irritable. Although alarming symptoms were not encountered, each child's response to physiotherapy and to the usual program of activities was far from at its best. When the interval between injections was longer than four days, complete spasticity returned, and hence the same obstacles to treatment appeared that were encountered before the drug was used. The length of time required for the return of these symptoms was governed somewhat by the size of the dose, and also by the degree and extent of the spasticity.

*Clinical data.* Repeatedly recorded observations showed that the drug had no immediate or delayed

TABLE 2. Optimum Maintenance Doses of Curare for Each of the Children.

CASE No.	AGE	WEIGHT	HEIGHT	PRIMARY SYMPTOMS	MAINTENANCE DOSE OF CURARE	
	yr.	kg.	cm.		mg.	mg./kg. body weight
1	7½	17.3	113.0	Spasticity, generalized, severe	56	3.3
2	12	30.0	134.5	Spasticity, generalized, severe	60	2.0
3	9	24.1	120.5	Spasticity, generalized, moderate	40	1.7
4	10½	35.5	127.0	Spasticity, lower extremities, severe	56	1.5
5	9	32.3	143.0	Spasticity, generalized, moderate	32	1.1
6	9	29.5	129.5	Spasticity, generalized, moderate	32	0.9

terminated on a body-weight basis. In the present group of patients, the optimum maintenance dose varied between 0.9 and 3.3 mg. per kilogram of body weight. These are larger maintenance doses than those used by others.

The constancy of response to individual maintenance doses in each child was striking. In no case was there diminished response or any alarm-

effects on pulse rate, respiratory rate, blood pressure or temperature.

### *Laboratory Studies*

*Psychologic tests.* Standard performance tests from the psychologic laboratory were used as aids in evaluating each child's response to varying amounts of curare. The pin board, peg ball and tracing boards were used, and the responses scored as described by Garrett and Schneck.<sup>11</sup> The results do not lend themselves to graphic portrayal in summary form in the present report, but in general, improvement in speed and accuracy of performance paralleled the clinical impression obtained otherwise.

*Other tests.* Various other laboratory tests, including blood counts, complete urinalyses, tests of renal function, blood chemical studies, electrocardiograms and electroencephalograms, showed no deviation from normal as a result of the use of curare.

### *Therapeutic Effect of Curare*

The results so far described have been specific responses to the administration of a particular drug. They fail utterly to depict the dramatic therapeutic response shown by the children in terms of improved relaxation during the muscle-training periods and during participation in their daily activities. On adequate maintenance dosage, clinical improvement was noted in every activity in which the child participated. During physiotherapy, the children enjoyed a fuller range of motion than previously; their co-ordination was smoother and more rhythmic. There was less resistance to passive exercise, and apparently increased muscle strength was noted in all children. The best clinical results appeared twenty-four hours after injection, when the initial lethargy and hypotonia had worn off. For the next three days motor performances were carried out with relaxation of antagonistic muscles and those not in use.

The subjective response to the treatment, as illustrated by the children's conversation, was interesting. Such remarks as "I feel light," "I'm happy" and "I feel easy" were frequently heard. As the effects of the drug wore off, the children spontaneously said that they were "feeling heavy again." It is significant that although as a group these patients are easily upset and ordinarily resistant to medical or surgical procedures, they were actually pleased to have a fairly large needle plunged into the muscles of the buttocks because of the favorable effects of the drug.

The experience of being able to carry out motor activities that were new and more extensive than those previously enjoyed was stimulating to

patients whose previous progress had been slow and discouraging. One boy (Case 6) had been anxious to spin a "jack," but had lacked sufficient control of his fingers to carry out this fairly skilled act. Under curare, he easily accomplished this, and was pleased and stimulated by the result. A nine-year-old girl who could walk only with difficulty had long wished to run up stairs. Under curare, she soon found that she was able to realize this ambition.

With muscles and limbs free to carry out constructive exercise, the children appeared to develop muscle strength and motor control. This persisted after the drug was stopped. One boy who had always held his arm tightly flexed across his chest was for the first time taught to hold it firmly on the arm of a chair while under the influence of curare. Four weeks after the drug had been discontinued, he still carried out this newly acquired act with assurance and confidence.

### *Combined Effect of Curare and Amphetamine*

Amphetamine sulfate in oral doses of 10 and 20 mg. daily was given to all the children during a period when they were regularly receiving maintenance amounts of curare. Four children (Cases 1, 2, 3 and 4) responded with increased output of energy and enthusiasm for daily activities, and resulting acceleration of motor performance. The response of these children to amphetamine simulated that noted in behavior problem children, and was in contrast to that reported by Nichols and Warson<sup>13</sup> on another group of spastic children who were not receiving curare, but who were studied under comparable conditions at the Bradley Home. However, 2 patients (Cases 5 and 6) responded to amphetamine, as those noted in the other series did, by becoming irritable and distractible, with corresponding decrease in efficiency of relaxation and motor performance.

### DISCUSSION

The treatment of children with cerebral palsy consists essentially of muscle training and the application of special educational procedures. These patients must be taught to do what other children acquire naturally in the way of motor co-ordination and efficient use of their bodies. The use of drugs that temporarily decrease pathologic neuromuscular activity and the employment of orthopedic operations or apparatus as mechanical aids to body function are always supplementary. Alone, they have no curative value, but their utilization may for the first time make it possible for a spastic child to profit from a training program. If curare is to have a place in the treatment of children with

cerebral palsy, it is a supplementary but nonetheless vitally important agent.

The present study confirms other recent but scattered reports that curare is now available for clinical use in well-standardized, potent and stable form. It can be safely administered to children with cerebral palsy in individually adjusted doses that are larger than those previously suggested in the literature. These large doses are effective in reducing muscle spasm over a period of several days, and require intramuscular injection but twice a week. Because curare relaxes the spasm of hypertonic muscles in doses insufficient to cause complete paralysis or respiratory embarrassment, treatment that is therapeutically efficient is not accompanied by the alarming symptoms of threatened collapse, which are a constant threat in truly paralytic doses of the drug. However, in the present state of knowledge, efficiency combined with safety is attainable only when the dosage for each child is determined by a noting of the patient's response to each of several gradually increasing doses, injected intramuscularly and starting at approximately 5 mg. Conservatism at present suggests that the adjustment of dosage as indicated in this study should be supervised by a physician thoroughly familiar with the behavior reactions of healthy as well as spastic children.

It is encouraging that, in these 6 cases, progress under physiotherapy was definitely accelerated by curare. When amphetamine was added, the accomplishments of 4 of these children were even further increased because of the additional "drive" that was imparted by the latter drug. This is an effect noted in physically intact children,<sup>12</sup> but it has not been noted in spastic children. Without curare, amphetamine presumably stimulates the same drive, but because of rigid, unmanageable limbs, the child is frustrated in his attempts to ac-

complish what he more ardently desires and as a result becomes irritable or sulky.

There was no evidence that any tolerance to curare was established through its continued use. The response of individual patients to specific doses in a uniform fashion was outstanding.

#### SUMMARY

A standardized, stable preparation of curare was injected intramuscularly in 6 children with cerebral palsy. The result was improved relaxation and reduction of spasticity in hypertonic muscles. By systematic adjustment of the dosage for each child, it was found that from 0.9 to 3.3 mg. of curare per kilogram of body weight resulted in relaxation lasting approximately four days. No toxic or dangerous effects were encountered under the regime employed, and response to muscle training and to the educational program was definitely accelerated.

## PARADOXICAL HEMATEMESIS\*

## Report of a Case

FRANK HINMAN, JR, M D †

BALTIMORE

IT is said that among every 100 patients who enter the hospital is one whose chief complaint is hematemesis.<sup>1,2</sup> About half these patients leave the hospital with a diagnosis hardly more exact than "hematemesis, source doubtful or unknown."

The reasons for this lack of exact localization of bleeding in patients who vomit blood warrant a brief review. Shaw<sup>3</sup> classifies the causes of hematemesis as follows: intrinsic gastroduodenal le-

hemorrhage from the stomach should be differentiated from esophageal bleeding or hemoptysis arising in the air passages and oropharynx. Blood from the latter structures may be swallowed and subsequently vomited. Localization rests on the objective examination of all possible sources of bleeding. Jackson et al.<sup>4</sup> wrote "Inferential methods of diagnosis are subject to a large percentage error. Objective examination of all accessible portions of the air and food passages should never be neg-

sions; splenohepatic disorders; blood diseases; swallowed blood from epistaxis or hemoptysis; and hyperpiesis. These are arranged in the order of their frequency, and Shaw excludes those of rare occurrence.

Of importance because potentially their condition can be diagnosed and consequently can be treated by specific methods are the patients who fall into the fourth category of Shaw's classification, namely, those who swallow blood and subsequently vomit it. These constitute the cases of what may be called "paradoxical hematemesis," since the blood does not come primarily from the stomach. Whether or not actual hematemesis has occurred is often difficult to determine, but true

lected." Information from the history may be pathognomonic and, when combined with confirmatory physical signs and roentgenographic examination, makes an exact diagnosis possible. As indicated below, however, this accuracy is not the rule.

Table 1 summarizes the diagnoses in 1139 cases of hematemesis abstracted from the reports in the literature of the last ten years and from the records of the Peter Bent Brigham Hospital since 1913. The latter include only those cases diagnosed specifically as hematemesis. All these cases have been grouped under three headings: "proved diagnosis," "doubtful diagnosis" and "no diagnosis made," more or less as the authors used the terms or as they appeared on the records. In 44 per cent of the 1139 patients, the diagnosis was proved by x-ray examination, esophagoscopy, operation or

\*From the Medical Clinic, Peter Bent Brigham Hospital.  
†Formerly clinical clerk, Peter Bent Brigham Hospital.

autopsy; this group needs no comment. Twenty-eight per cent of the patients were classified as "doubtful," and no diagnosis was made in another 28 per cent. In other words, for more than half the patients with hematemesis, no exact diagnosis was made.

The "doubtful" group is composed of patients with a history of ulcer but lacking x-ray or operative confirmation. Many of these patients were classified as having peptic ulcer because of the history of indigestion and because of the frequent incidence of this disease. The regimen for the treatment of ulcer is fairly nonspecific and generally supportive in the majority of cases, so that this lack of exactness is harmful only in the small group of patients who have advancing lesions higher in the food passages.

Among the 28 per cent of patients grouped under the heading "no diagnosis made" are those with a well-substantiated history of alcoholism and an enlarged liver, but without objective proof that esophageal varices were present. The cases in which the diagnosis of ruptured varix was made or suggested (the second group in Shaw's<sup>3</sup> classification) are divided about equally between the "proved" group in which x-ray examination or esophagoscopy was diagnostic, and that of "no diagnosis made," in which these examinations either were not made or yielded no definite findings. The latter group contains the overlooked lesions causing hematemesis, such lesions being esophageal ulcers, carcinomas, diverticulums, pulmonary lesions, vascular disorders and pharyngeal erosions. Ruptured esophageal varix is often a diagnosis of exclusion.

The rationality of Jackson's<sup>4</sup> advocacy of thorough objective examination of all possible sources of the bleeding is admirably illustrated by the following case.

CASE REPORT

M. J. G., a 60-year-old man, was admitted to the Peter Bent Brigham Hospital on June 15, 1939. He had long been in the habit of drinking at least 8 ounces of whiskey several days a week, but he had been well, had lost no weight, and had worked, as a mason's helper, until the onset of his illness. His appetite had been fair, and he had had no indigestion. Three days before entry, he had periumbilical cramps, which lasted 1 day. Twenty-four hours before admission, he vomited dark clotted blood. He repeated this at intervals until admission, losing in all about 250 cc. of blood. The blood was expelled without nausea or cough; it simply welled from his mouth. He was given morphine in the hospital, and the hematemesis ceased. Examination showed only questionable increase in the size of the liver and bilateral, solitary, firm cervical nodes. X-ray films of the chest and abdomen after a barium meal showed no changes from the normal. After an uneventful course in the hospital, the patient was dis-

charged with the probable diagnosis of cirrhosis of the liver and rupture of an esophageal varix.

One year after discharge, the patient reported to the Outdoor Department complaining that during the last 6 months the right cervical lymph node had increased in size. Examination and biopsy demonstrated squamous-cell carcinoma of the right tonsil. He was given 4000 r of roentgen therapy, with only temporary improvement; in fact, 1 month after the termination of therapy, a smooth, round mass was found at the base of the tongue.

The last (and diagnostically decisive) admission was on February 4, 1941. For 3 days, the patient had "brought up" bright-red blood intermittently, and the day before entering he had expelled about 500 cc. of dark blood mixed with gastric contents. That afternoon, he felt weak and passed several tarry stools. On admission, he had a thick tongue, with a firm, rounded mass on the right lateral margin extending backward to the base of the tongue and onto the lateral wall of the pharynx. The palatine fossa on the right was "punched out." Firm nodes were felt in the neck, bilaterally. X-ray examination showed no abnormality of the esophagus, stomach, duodenum or lungs but, with the patient swallowing barium, demonstrated what "appeared to be a large ulcerated area in the region of the right tonsil." At no time while the patient was in the hospital could actual bleeding from the pharynx be seen, but no further hematemesis occurred. All observers believed that the carcinoma of the tonsil, extending into the tongue, had ulcerated and bled, the blood being swallowed and later regurgitated.

Two comments are appropriate. In the first place, the difficulties in making the correct diagnosis are typical. An equivocal history from a patient who had an alcoholic past and a large liver, combined with hematemesis, seemed to make the diagnosis of bleeding from an esophageal varix obligatory, in spite of the lack of positive evidence by x-ray examination or esophagoscopy. Yet all that was needed to make the correct diagnosis on

TABLE 2. Incidence of Bleeding in Carcinoma of the Tonsil.

Total admissions	124,783	15,291	(Not known)
Cases of carcinoma of tonsil	7	100	1226
Cases with hemoptysis	2	2	4
Cases with hematemesis	1	0	0

\*Admissions limited to cases of cancer.  
†Pack and LeFevre<sup>9</sup> (1930), New<sup>10</sup> (1931), Coutard<sup>11</sup> (1932), Mattick<sup>12</sup> (1939), Schall<sup>13</sup> (1934), Duffy<sup>14</sup> (1934) and Richards<sup>15</sup> (1936).

the first admission was an objective search with all possibilities in mind.

Secondly, the occurrence of bleeding from carcinoma of the tonsil is very rare. Table 2 summarizes the cases at the Peter Bent Brigham Hospital (1913-1941) and the Collis P. Huntington Memorial Hospital (1930-1940) and from the litera-

ture Hemoptysis, caused by carcinoma of the tonsil, is unusual, and no report of hematemesis from this source was found in the literature during the last twenty-five years, although most authors make the statement that bleeding with subsequal hematemesis may occur from such pharyngeal sources. Speese and Skilern<sup>16</sup> report the case of an unconscious alcoholic patient who was brought in after vomiting a quart of dark blood mixed with gastric contents. At once, the diagnosis of cirrhosis of the liver with rupture of an esophageal varix was made. Later, however, careful examination showed that the patient had lacerated a coronary artery of the lip, that the blood had trickled down his throat while he was unconscious, and that he had vomited it.

Paradoxical hematemesis is recorded infrequently, but the diagnosis can be made more frequently if the possibility is kept in mind.

#### SUMMARY AND CONCLUSIONS

Hematemesis as a presenting symptom and a final diagnosis is reviewed by drawing on the records of the Peter Bent Brigham Hospital and on the experience recorded in the literature.

Emphasis is placed on the need for consideration of extragastric sources of bleeding. Although paradoxical hematemesis is relatively infrequent, the possibility should be borne in mind so that an

extragastric source will not be overlooked on routine examination.

A case of paradoxical hematemesis is reported in which ulceration in a carcinoma of the tonsil was the source of bleeding—an exceedingly rare occurrence.

#### CLINICAL NOTE

##### CHEMOTHERAPY IN TYPHOID FEVER\*

EGON E. KATTWINKEL, MD †

WEST NEWTON, MASSACHUSETTS

THE remarkable progress of chemotherapy as a science and the advent of new chemotherapeutic agents raise interest regarding this new form of treatment in all bacterial diseases. The literature contains few reports of its value in the treatment of typhoid fever and the sterilization of carriers. The success of sulfaguanidine in the following case justifies its report.

Saphir and Howell<sup>1</sup> and Enright<sup>2</sup> report apparent cures of two typhoid carriers with soluble idio-phthalein, in one case after failure with sulfanilamide. Levi and Willen<sup>3</sup> report the cure of a

carrier with sulfaguanidine after failure with soluble idio-phthalein, cholecystectomy and appendectomy.

#### CASE REPORT

Mrs J. D., a 39 year old housewife, had always been well except for a peptic ulcer in 1930 and colitis with blood and mucus in May, 1940. The latter diagnosis was verified by x-ray study. Apparent cure resulted from the use of belladonna, diet and rest. The stools were negative for amebas.

On April 1, 1941, the patient had a "cold," which improved during the next week. On April 5, she had chills and began running a daily temperature between 102 and 103°F. There was frequency and dysuria. On April 14, rose spots developed, and the next day the blood culture was positive for *Escherichia typhosa*. The subsequent clinical and laboratory findings are shown in Figure 1.

Because of persistent colon bacilluria, the patient was given several courses of sulfathiazole and sulfanilamide, these failed to clear the stools of *E. typhosa*. It was believed that the spiking temperature during the 3rd and 6th weeks of illness was due either to an exacerbation of typhoid fever or to pyelitis. A slight macular rash

\*From the Newton Hospital Newton Massachusetts

‡While in the hospital this patient was for a time under the care of Drs. L. S. Miller and A. R. Fried

appearing on the 28th day of illness was thought to be due to sulfathiazole therapy. An intravenous pyelogram on May 27 was negative for obstruction or renal damage, except for slight stasis in the right kidney.

On May 21, the patient suddenly developed a partial left hemiplegia following 2 days of numbness of the left

course of the disease and failed to clear the stools of *E. typhosa*. The stools became and remained negative after eight days of intensive sulfaguani-dine therapy.

65 Sterling Street

FIGURE 1.

arm. Lumbar puncture on May 23 was essentially negative. This episode was thought to be due to cerebral thrombosis, and the hemiplegia gradually disappeared in 2 weeks.

On May 31, the patient developed phlebitis of the left leg. Because of the lack of fever, this may have been a sterile thrombosis.

A Graham test showed a nonfunctioning gall bladder.

Because of persistently positive stool examinations for *E. typhosa*, the patient was given sulfaguanidine in large doses from June 2 to 16, and on June 9 the stools became negative and remained so. (Monthly stool cultures up to and including February 25, 1942, have been negative.)

When seen on July 12, the patient had gained 12 pounds and was symptom free except for slight weakness of the left cheek, slight swelling of the ankles at night and falling hair.

Up to the present time, investigation by the Massachusetts Department of Public Health has failed to reveal the source of this infection. The likeliest cause was food eaten 10 days before onset, while the patient was at a bridge party.

SUMMARY

A case of typhoid fever is reported. Sulfathiazole and sulfanilamide in no way influenced the

## MASSACHUSETTS MEDICAL SOCIETY

## PROCEEDINGS OF THE COUNCIL

Stated Meeting, February 4, 1942

A STATED meeting of the council of the Massachusetts Medical Society was held in John Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, February 4, 1942. The meeting was called to order at 10:30 a.m. by the president, Dr. Frank R. Ober, Suffolk; 207 councilors were present (Appendix No. 1).

The Secretary presented the record of the meeting of the Council of October 1, 1941, as published in the *New England Journal of Medicine*, issue of November 6, 1941. On a motion by the Secretary and a second by a councilor, the Council approved the record as published.

*Report of Auditing Committee*

There was no response from the chairman, Dr. LeRoy A. Schall, Middlesex South.

*Report of Treasurer*

The report of the Treasurer (Appendix No. 2) was presented by Dr. Charles S. Butler, Suffolk. The report was accepted by the Council on the motion of Dr. Reginald Fitz, Suffolk.

The Secretary announced that his office is compiling a list of the fellows of the Massachusetts Medical Society who have entered the armed forces of the United States. He asked for the co-operation of the district secretaries in his endeavor to make this list complete. He added that at some future time the Council might wish to take particular notice of this patriotic service.

President Ober, at this point, called a meeting of the Committee on Public Relations. He asked the members of this committee to retire to the offices of the Society on the ground floor.

## REPORTS OF STANDING COMMITTEES

*Executive*

The Secretary presented the report of the Executive Committee (Appendix No. 3).

He spoke of a telegram which President Ober sent to the Governor of Massachusetts, the Honorable Leverett Saltonstall, on December 7, 1941, pledging the aid of the Massachusetts Medical Society in the crisis which had arisen that day. He read the Governor's answer. He announced that the Executive Committee had approved. He moved that the Council likewise approve this act

of the President. This motion was seconded by a councilor and carried.

The Secretary was directed on December 29, 1941, to send a telegram to the President of the United States embodying a resolution which had on that date been adopted by the Executive Committee. He read the telegram and President Roosevelt's answer. He moved that the Council likewise approve this act of the Executive Committee. This motion was seconded and carried.

He announced that the Executive Committee had reviewed certain matters which were to be presented by the Committee on Public Relations. He added that the Executive Committee commended the recommendations contained therein to the earnest consideration of the Council.

He reported on a special meeting of the Executive Committee which was held February 4, 1942, at 9:30 a.m. He read a resolution which was adopted by the Executive Committee. He added that the committee recommended its adoption by the Council and he so moved. The motion was seconded by Dr. Brainard F. Conley, Middlesex South.

Dr. Albert A. Hornor, Suffolk, in speaking for the adoption of the resolution said that he did not believe that we can hospitalize everybody who would be entitled to hospitalization under such a provision of taxation. He added that it was his belief that, if such a burden were thrown on hospitals at this time when we are anxious to be ready to take care of sudden War emergencies, hospital service would break down. He spoke of the present shortage of nurses and of the other difficulties to which the situation would give rise.

Dr. Channing Frothingham, Suffolk, inquired whether this matter had been considered before 9:30 that morning. President Ober answered, "No." Dr. Frothingham then said, "This is simply asking us to vote on a very important question without any consideration other than what the Executive Committee gave it at 9:30 this morning." He added that we really have not any definite program presented to us by the Social Security Department so that we may know what this is all about. He then asked if this was correct. President Ober by way of answer said that we have intimations of what the program is going to be. Dr. Frothingham then said that it is out of all

serious reason to introduce such a resolution now and ask us to vote on something that we know nothing about.

Dr. Conley in speaking in favor of the resolution called for confidence in the judgment of the Executive Committee and commended the committee for its alertness.

Dr. Charles C. Lund, Suffolk, expressed himself as being impressed by the seriousness of the subject under discussion. He asked that the Council be informed as to the background upon which this action of the Executive Committee was based. President Ober asked Dr. Michael A. Tighe to respond. Dr. Tighe said that the point which Dr. Lund made was well taken. It was expected by the Executive Committee that, in the debate which the presentation of the resolution would provoke, the background of knowledge which the Executive Committee possessed would be made available to the Council.

A few weeks ago there was a conference in Washington presided over by Mr. Altmeyer of the Social Security Department of the United States Government. Attending that conference were representatives of the American Hospital Association, Catholic Hospital Association and certain representatives of Blue Cross outfits from various parts of the country. Those attending that conference came away from it with the definite impression that it was the intention of the Social Security Department to call upon Congress for an extension of the present social-security coverage so as to include much greater numbers than it does now and so as to provide hospitalization for all so covered. The figures, as to those who would be covered in the extension, left the impression with the Executive Committee that this might well be the first step in the realization of the program presented some time ago in the report of the Interdepartmental Committee. We found much fault with this report when it was presented. You will remember that compulsory sickness insurance was an integral part of it. The Executive Committee was well aware that this matter had not reached the stage wherein a definite piece of legislation had been introduced into the Congress. Its purpose is to combat an idea which, if followed in its natural sequence, would be subversive of certain principles for which our organization stands.

Dr. John Homans, Suffolk, expressed the thought that it might be possible to add to the resolution a statement to the effect that the medical profession realizes the need of some form of prepaid medical care and is working to meet that need.

Dr. Leroy E. Parkins, Suffolk, asked that the resolution be read again.

President Ober at this point stated that the American and Catholic hospital associations, together with the Blue Cross associations and the American Medical Association, are cognizant of this matter and feel that we should do something about it before it starts.

The Secretary again read the resolution.

A demand for the question arose from several members of the Council. The question was put and the resolution adopted.

Dr. William M. Collins, Middlesex North, moved that the Committee on State and National Legislation, together with the officers of the Society, be instructed to follow closely the progress of this proposed legislation, using all the machinery at their command to oppose it. This motion was seconded by a councilor.

Dr. Lund offered the following amendment:

That the Committee on State and National Legislation and other officers of the Society be instructed to oppose such parts of the proposed legislation as seem harmful to the public and profession.

There was considerable discussion as to the advisability of publishing the resolution as proposed. Dr. Henry C. Marble, Suffolk, moved that it be not published in the minutes of this meeting but shall be written up. Considerable discussion followed participated in by Drs. Marble, Conley, Bearse, Chapman, Frothingham and Leavitt. Dr. Lund's amendment was recorded by a Councilor and carried on a show of hands. Dr. Collins's motion as amended was carried by vote of the Council.

### *Membership*

The report (Appendix No. 4), which was presented by the chairman, Dr. G. Colket Caner, Suffolk, recommended that twenty-three fellows be allowed to retire as of December 31, 1941, that seven be allowed to resign as of December 31, 1941, that the dues of ten fellows be remitted, that thirty-three be deprived of the privileges of fellowship, that ten fellows be allowed to change their membership from one district society to another without change of legal residence and that six fellows be recommended for readmission to fellowship.

Dr. Caner moved the adoption of the recommendations. The motion was seconded by a councilor. Dr. William E. Browne, Suffolk, expressed surprise that the committee's list contained the name of Dr. Seymour I. Zonn as one who had been dropped for nonpayment of dues. He asked Dr. Caner if this man had been notified of the fact that his dues were in arrears. Dr. Caner replied

that he had been so notified. Dr. Cancr's motion was adopted.

### *Financial Planning and Budget*

The report (Appendix No 5) was presented by the chairman, Dr. John Homans, Suffolk, who moved its adoption. The motion was seconded by a councilor.

Dr. Bearse inquired why the amount \$2000 set aside for medical defense was so large. Dr. Homans explained that this sum has been set aside against the possibility that it may be required this year.

Dr. Homans's motion was carried by vote of the Council.

### *Publications*

The report (Appendix No 6) was presented by the chairman, Dr. Richard M. Smith, Suffolk. This report announced that Dr. John F. Fulton, of New Haven, had been selected to give the Shit-tuck Lecture in 1942. It likewise spoke in praise of Dr. Robert N. Nye, managing editor of the *New England Journal of Medicine*. Dr. Smith moved the adoption of the report. The motion was seconded by a councilor and adopted by vote of the Council.

### *Arrangements*

This report (Appendix No 7) was presented by the chairman, Dr. William T. O'Halloran, Suffolk.

This report announced that the annual meeting of the Council will be held on the evening of May 25, 1942, and that the annual meeting of the Massachusetts Medical Society will be held on May 26 and 27, 1942. Both these meetings will be held at the Statler Hotel in Boston and promise to be larger than ever and to cost less.

### *Ethics and Discipline*

This report (Appendix No 8) was presented by the chairman, Dr. Ralph R. Stratton, Middlesex East. The report spoke of the three full-day meetings which the committee had held and said that the cases considered fell into four groups: first, those having to do with the ethical nature of proposed publications; secondly, those which were concerned with complaints against fellows for improper advertising; thirdly, those which grew out of alleged exorbitant charges by fellows; and, fourthly, those that charged violation of Article IV of the Code of Ethics of the Massachusetts Medical Society.

The report further spoke of the amicable way in which the matters referred to the committee had been settled.

Dr. Stratton moved the adoption of the report. The motion was seconded by a councilor and carried by vote of the Council.

President Ober at this point stressed the importance of the business before this meeting of the Council and urged all members to return to the meeting after luncheon.

### *Medical Education*

The report (Appendix No 9) was presented by the chairman, Dr. Robert T. Monroe, Norfolk.

This report spoke in praise of Dr. John P. Monks, who resigned as chairman, to enter the United States Navy.

It says that the membership of the Massachusetts Medical Society has grown during the last ten years from 4750 to 5676, an increase of nearly 20 per cent.

The number of applicants who have become fellows and who are graduates of approved schools has fallen off sharply in the last two years. From 1932 to 1939, they varied from 200 to 230 annually. In 1940, they fell to 179, and in 1941, to 115. During the same decade the number of graduates of unapproved domestic schools has remained essentially unchanged—22 to 38 in each year. The number of graduates of foreign medical schools rose from 4 or 5 through 1939 to 28 in 1940 and 60 in 1941.

The committee believes that admission to fellowship under the new by laws seems to be working out better than under the old and thinks it should be allowed to continue to exercise its discretion in the approval of candidates.

The committee is convinced that it would be a grave error to increase the time necessary for a reputable foreign physician to be resident in this country before being allowed to apply for fellowship in the Society.

The report concludes with the statement that the number of poorly educated graduates of unapproved domestic medical schools who enter the Society is too great.

It was moved and seconded that the report be accepted and so ordered by vote of the Council.

### *State and National Legislation*

The chairman, Dr. Henry C. Marble, Suffolk, no report.

### *Public Health and Public Education*

The report (Appendix No 10) was presented by the chairman, Dr. Francis P. Denny, Norfolk.

The report recommended that the weekly broadcasts known as "Green Lights to Health" be discontinued on the completion of the present pro-

gram, which will be about March 1, 1942. It says that the committee arrived at this conclusion because the morning hour assigned by broadcasting stations for these talks was much less satisfactory than the late afternoon time, which had formerly been given up to this matter, because the field of obstetrics had been ruled out entirely, because certain physiologic functions were no longer possible of reference and, finally, because the amount of good accomplished did not seem to justify the time which members of the Society would have to give in preparing the broadcasts—this latter in view of the numbers entering the service and the consequent increased demands on those who remained at home.

On motion by Dr. Denny and a second by a councilor the report was accepted and the recommendation adopted by vote of the Council.

### *Medical Defense*

Chairman, Dr. Arthur W. Allen, Suffolk, no report.

### *Permanent Home*

Chairman, Dr. William H. Robey, Suffolk, no response.

## REPORTS OF SPECIAL COMMITTEES

### *Cancer*

The report (Appendix No. 11) was presented by the chairman, Dr. Shields Warren, Suffolk.

The report spoke of the enthusiasm which was aroused generally by the publication of *The Cancer Manual for Practitioners*.

The committee feels that the Society should not be asked to support at this time the intensive campaign proposed for Massachusetts by the Women's Field Army. The committee believes that the compulsory reporting of cancer cases is not advisable.

The committee points to the excellent work being done by the state-aided cancer clinics throughout Massachusetts and says that these clinics are striking examples of how much benefit accrues to the public by this type of co-operation between the medical profession and public-health authorities.

Finally, the committee recommends that the president of the Massachusetts Medical Society be authorized to appoint a representative of the Society, preferably a member of the Committee on Cancer, to visit the various state-aided cancer clinics and report to the Society on their present state.

Dr. Warren moved the acceptance of the report and the adoption of the recommendation.

The motion was seconded by a councilor and so ordered by vote of the Council.

### *Public Relations*

This report was in two sections. Section A (Appendix No. 12A) was presented by the secretary, Dr. Elmer S. Bagnall, Essex North. It announced that the committee had given preliminary consideration to a postpayment plan for medical care sponsored by the banks and asked that the President be authorized to appoint a committee of three from among the members of the Massachusetts Medical Society to confer with the bank committee about this plan and that this committee report to the Council through the Committee on Public Relations.

Dr. Bagnall moved the adoption of this recommendation. The motion was seconded by a councilor and so ordered by vote of the Council.

Dr. Bagnall pointed out that each member of the Council had received material prepared by the committee on the subject of tax-supported medical care. He asked to be excused from reading it as a means of saving time. Dr. Bagnall moved that the recommendations contained in this part of the report be adopted. The motion was seconded and so ordered by vote of the Council. He also pointed out that in some localities cases in the insurance fields which involved hospitalization in wards had given rise to certain difficulties. The report recommended that the committee appointed to confer with the Massachusetts Hospital Association be instructed to meet with that body with a view to straightening out the difficulties involved. Dr. Bagnall moved the adoption of the recommendation. It was seconded by a councilor and so ordered by vote of the Council.

Section B (Appendix No. 12B) was presented by the chairman of the Special Committee on Prepayment Medical-Care Costs Insurance, Dr. James C. McCann, Worcester. This report contained nine recommendations which are concerned with the further development of the proposed Massachusetts Medical Service Corporation.

These recommendations are as follows:

1. That permission be granted the Massachusetts Medical Service Corporation to co-ordinate its activities with the Blue Cross relative to (1) the presentation of joint contracts to subscribers and (2) administrative functioning and expense. This shall be done with each group retaining (1) its distinct independent corporate identity and (2) the right to issue separate contracts, the relation of the two corporations to be determined on a contract basis.
2. That a special committee be appointed by the Executive Committee to select an executive director.

3. That authority be granted to the special committee to hire an actuary, provided that sufficient actuarial data are not made available to the committee through the Massachusetts Division of Insurance

4. That income levels for eligibility for medical service contracts (contrasted to medical indemnity contracts) be set up at \$2000 for an individual and \$2500 for a family. At present, only medical indemnity, and not medical service, contracts shall be offered above these levels

5. That contracts be prepared and presented on the following basis: (1) the quick preparation of a surgical contract for hospital surgical expense, (2) the preparation, as quickly as feasible, of a total hospital medical care contract to cover all medical fields incidental to hospital expense, (3) the careful slow preparation of a comprehensive medical-care contract covering total medical-care expense in the home, office and hospital, to be presented when the Massachusetts Medical Society so determines

6. That such sums as are indicated by the Commissioner of Insurance (presumably between \$10,000 and \$25,000) be loaned to the Massachusetts Medical Service Corporation by the Massachusetts Medical Society, and that other funds be raised by an enrollment fee from the participating physicians (to be returned to physicians enrolling within a given period of time, when as and if the corporation is financially able to do so)

[To complete action on this proposition and establish the Corporation, it is evident from the facts presented and from information received from the Commissioner of Insurance that but two subsequent steps are required: First, the preparation of contracts and, second, the preparation of a fee schedule]

7. That contracts be prepared

- (a) Between the physician and the Corporation,
- (b) Between the subscriber and the Corporation,
- (c) Between Blue Cross and the Corporation

8. That the contracts mentioned above and the statement to the Commissioner on the unit system be prepared and made effective by action at a combined meeting of the Committee on Public Relations and the Executive Committee

9. That a basic fee schedule be prepared, approved and put into effect for the Society by a group consisting of

- (a) The Committee on Public Relations
- (b) The Executive Committee
- (c) Appointees by the President in number and type to achieve an effectively balanced professional group, properly representing the general physician and the specialists in medicine

[The fee schedule is a basic proposition. (1) All are related to the New York Workmen's Compensation Schedule, which is accepted by physicians, government authorities and social workers as fair. (2) Various schedules are moderately lower in agricultural sections, and the same or moderately up in industrial sections. (3) It is anticipated that the Massachusetts schedule will be primarily based on the Michigan schedule, there must be a basic table accepted to be modified by experience after the Corporation begins to function. (4) There must also be presented to the Commissioner a statement of the method of compensation of the physician, which shall be on the unit system related to the accepted fee schedule.]

Dr McCann discussed each recommendation at considerable length and after offering, in each case, a most convincing argument, moved its adoption. In each instance his motion was seconded and so ordered by vote of the Council.

Recommendation No 5 was discussed by Dr. Channing Frothingham. He spoke as follows:

Unfortunately this plan so well prepared by Dr. McCann falls far short of the original ideas of the Council.

The records of the Council show that all the votes since April, 1939, on this subject make it clear that the Council has been interested in the development of a plan for the delivery of medical care on a prepayment basis. From the beginning this movement had the following objects in view:

1. To give more of the people of moderate means better medical care

2. To give better remuneration to physicians than they now receive for the medical care of people of moderate means

3. To permit more people to leave the charity clinics and return as private patients to physicians

4. To ally some of the agitation for governmental interference in the practice of medicine by satisfying more of the population

Although Dr. McCann's plan visualizes the possibility of comprehensive medical care at some future date, at present it simply offers some financial protection to those who are unfortunate enough to need surgery. Therefore, instead of offering medical care to the many, it only offers some financial protection to the few. This plan will not give better remuneration to the great mass of physicians as it only involves the surgeons. It will not make it possible for some of those patients who are now forced to go to the charity clinics for medical care to again become private patients of their own physicians. It will do very little more toward furthering the utilization of our ever increasingly effective preventive medicine. Further more it will benefit only a few of those people who are agitating for governmental interference in the practice of medicine and so accomplish little in averting this threat.

The question arises, Is it possible to develop a comprehensive medical care plan on a sound financial basis so that the original ideals of the Council can be fulfilled? From actual experience in several parts of the country it has been established that with from 10,000 to 20,000 subscribers a medical-care plan can be developed which will produce these results. The figures available from the White Cross experiment substantiate this. The White Cross operating on its adjusted pediatric and obstetric charges would with 20,000 subscribers pay its physicians adequately. There seems to be little doubt that subscribers to a scheme sponsored by the Massachusetts Medical Society would exceed these figures.

Another pertinent question is, Will the development of this plan before us make it more difficult eventually to develop a comprehensive medical care plan? There is some evidence to suggest that these plans for insurance to cover surgical fees lead to a marked increase in the amount of unnecessary surgery. In our state, in which so many poorly trained men are allowed to practice surgery, this possible increase in unnecessary surgery may be a real danger, especially if the Society insists upon free choice of physician rather than free choice of qualified physician. Therefore should this plan not succeed it might well give a black eye to the whole program of

furnishing comprehensive medical care on a prepayment basis.

This is the time at which the Council should decide whether it wants a comprehensive medical-service plan as it has always voted it did, or whether it wants a plan just to cover the financial emergency of unexpected surgery. If the Council prefers a medical-service plan, it should not vote to put into operation the plan as here presented, but should insist that the entering wedge should be the development of a plan for providing general medical care on a prepayment basis to certain groups. With the data already received by Dr. McCann and the experiences available regarding medical-service plans, it should be a relatively easy matter to develop such a plan in a short time.

In answer to a councilor Dr. McCann said that "one," "two" and "three" in Recommendation No. 5 outlined the sequence in which the Massachusetts Medical Service Corporation should offer contracts to the public. First, it should offer a surgical, obstetric and x-ray coverage only because this was at this time the safe way to approach the matter. When this part of the plan had been in operation for a while, sufficient experience would be gained so as to enable the Corporation to extend its coverage to the care of all types of hospitalized cases. The further experience thus gained he hoped would ultimately enable the Corporation to cover all types of sickness whether cared for in the hospital, home or office.

Dr. Norman A. Welch, Norfolk, spoke in favor of Recommendation No. 5 and emphasized Dr. McCann's statement that the type of coverage outlined in number one of Recommendation No. 5 was what the people really wanted at this time.

Dr. Homans asked for a discussion of Recommendation No. 6 before it was acted on by the Council. He wanted to know of the guarantee to the Massachusetts Medical Society that this sum of \$25,000 would be returned. He likewise wanted to know whether further sums would be asked for. Dr. Ober suggested that this money might be borrowed from a bank by the Massachusetts Medical Society at 4 per cent interest. He added that if the Massachusetts Medical Society put up the collateral the money could be had at a rate of 2½ per cent.

Dr. Charles J. Kickham, Norfolk, said that the Council voted to establish the Massachusetts Medical Service Corporation. The Insurance Commissioner requires a reserve of \$25,000 to be set up before such a Corporation can do business. He added that there was nothing else for us to do but to vote the loan. Dr. Homans suggested that the money might be obtained from some charitable fund. Dr. David L. Halbersleben, Norfolk, in objecting to this said that the Corporation should be in control of the Society itself.

Dr. Lund pointed out that \$25,000 means \$5.00 per member. He added that an assessment of \$5.00 per member would see this program through.

Dr. George L. Schadt, Hampden, asked if Dr. McCann had any information as to how this money might be raised. He answered that the Michigan State Medical Society had financed its own plan and that this phase of the subject had been discussed in the Committee on Public Relations. He added that the committee believed that as this was the Massachusetts Medical Society's program, its funds should be utilized for this purpose.

Dr. Edward P. Bagg, Hampden, spoke of how fruitful this meeting had been and moved that a special assessment of \$5.00 be levied on each member to make this movement possible. This motion was not seconded.

Dr. J. Harper Blaisdell, Middlesex East, directed certain questions to the Treasurer as to the net quick assets of the Society. Dr. Butler replied that the general fund of the Society is about \$132,000 and that this amount is largely in securities.

Dr. Blaisdell said that we have to come to a point where we either have to "put up or shut up." "We have to fish or cut bait." He added that this money should be voted from the free moneys lying in our account.

Dr. Homans wanted to know whether or not the \$25,000 spoken of was the limit of our obligation.

Dr. Butler said that, in the event that this money was loaned, it ought to be made clear that we would get it back again.

Dr. Conley said that this amounted to lending money to ourselves and added that it got to a point where we cannot trust ourselves with our own money.

At this point there were cries, "Question—question." The question was put and so ordered by vote of the Council, as previously recorded.

President Ober instructed the councilors that their district societies should create local professional-service committees in the near future. The by-laws of the corporation provide for a local administrative unit of nine persons—five physicians and four laymen. The former constitute the district professional-service committee; however, any additional number of physicians may be added to this committee, if it is deemed necessary. He added that such committees must be formed, by appointment or by election, in all districts before the corporation can begin to function.

#### *Postgraduate Instruction*

The report (Appendix No. 13) was presented by the chairman, Dr. Reginald Fitz, Suffolk. It

spoke of the wide interest shown in the New England Postgraduate Assembly which was held on October 29 and 30, 1941. The total attendance was 720 and seven states were represented. The receipts were \$301.41 more than the expenditures.

The postgraduate extension program for the present year has been organized in two divisions. One is financed by the Society for which a registration fee of \$5.00 will be charged and one, having to do with venereal disease, is sponsored by the State Department of Public Health; for this latter there will be no charge. Nine districts have signed up for the general course and three for that concerned with venereal disease. These courses are open to all legally registered physicians.

The committee has as yet arrived at no decision in the matter of a postgraduate assembly for next fall.

Dr. Fitz moved the adoption of the report. The motion was seconded and so ordered by vote of the Council.

#### *Physical Therapy*

There was no response from the chairman, Dr. Franklin P. Lowry, Middlesex South. (See Appendix No. 14.)

#### *Expert Testimony*

Chairman, Dr. George L. Schadt, Hampden, no report.

#### *Automobile Insurance Claims*

Chairman, Dr. Henry C. Marble, no report.

#### *Convalescent Care*

Chairman, Dr. T. Duckett Jones, Norfolk, no report.

#### *Industrial Health*

Chairman, Dr. W. Irving Clark, Worcester, no response.

#### *Army Medical Library and Museum*

Chairman, Dr. Henry R. Viets, Suffolk, no response.

#### *Study of the Practice of Medicine by Unregistered Persons*

Chairman, Dr. Richard Dutton, Middlesex East, no report.

#### *Committee to Meet with Massachusetts Hospital Association*

Chairman, Dr. Howard M. Clute, Suffolk, no report.

#### *Medical Preparedness*

The report (Appendix No. 15) was presented by the chairman, Dr. Reginald Fitz, Suffolk.

Dr. Fitz has nominated the following members of the Massachusetts Medical Society who will serve with him as a state committee to promote in Massachusetts the work of the Procurement and Assignment Service:

Dr. Howard M. Clute, Suffolk  
Dr. John J. Curley, Worcester North  
Dr. Edward L. Kickham, Norfolk  
Dr. Dwight O'Hara, Middlesex South  
Dr. Walter H. Pulsifer, Plymouth

These nominations will be subject to confirmation by Mr. McNutt, head of the Service at Washington.

On January 9, 1942, Dr. Fitz addressed each of the eighteen district presidents asking that a procurement and assignment committee be set up in his district. He reports that to date such committees have been organized in twelve districts.

On January 30, 1942, the names of forty-five physicians under the age of thirty-six, who had already enrolled with the Procurement and Assignment Service at Washington, were sent to Dr. Fitz "for scrutiny" as to the availability for "services elsewhere in the interest of the national emergency"—so as "to avoid the indiscriminate dislocation of practitioners who are in essential capacities." The names on this list have been submitted by Dr. Fitz to their respective districts and four of these districts have already reported. Dr. Fitz added that the results to date reflect credit on the Society.

He moved the acceptance of the report. The motion was seconded and so ordered by vote of the Council.

#### *Committee to Examine WPA Records*

Chairman, Dr. Guy L. Richardson, Essex North, no report.

#### *Maternal Welfare*

Chairman, Dr. Judson A. Smith, Suffolk, no response.

#### *Study of Practice of Medicine*

Chairman, Dr. Dwight O'Hara, Middlesex South, no report.

#### *Committee to Revise the By-Laws*

The chairman, Dr. Blaisdell, gave a verbal report in which he said that a rough draft of the by-laws was about ready. He said that when these by-laws are finally presented, many changes will be noted. He added that there will be an attempt to clarify the "five-year rule," that a new Standing Committee, to be known as the Hospital Relations Committee, will be recommended, that an attempt will be made to clarify the duties of the Secretary and Executive Secretary, that the du-

ties of the Executive Committee will be dealt with, that there will be a detailed consideration of the budget needs of this Council and finally that the status of assessments in district societies in relation to membership will be indicated.

He expressed the need for a special meeting of the Council, promising that the contemplated changes will be in the hands of the councilors two weeks before that meeting.

The Secretary pointed out that it also was the intention of the committee to call into conference all those committees which might be affected by the changes, preliminary to the presentation of the final draft to the Council.

Dr. Blaisdell moved that his report be accepted as a report of progress. The motion was seconded and so ordered by vote of the Council. Dr. Blaisdell moved that a special meeting of the Council be convened at such time as the President shall determine. The motion was seconded and so ordered by vote of the Council.

#### *Committee on Rehabilitation*

The report (Appendix No. 16) was ordered by the chairman, Dr. William E. Browne, Suffolk.

The report spoke of many conferences which the committee held with Professor Curtis Hilliard of the Massachusetts Committee on Public Safety and reiterated the Massachusetts Medical Society's time-honored stand of being privileged to be of assistance to those afflicted by disease or injury. Dr. Browne moved the adoption of the report. The motion was seconded and so ordered by vote of the Council.

Dr. Browne moved that the Committee on Rehabilitation be instructed to confer with Selective Service officials as to how the Massachusetts Medical Society might best co-operate in the matter of rehabilitation. The motion was seconded by a councilor and so ordered by vote of the Council.

Dr. Ralph M. Chambers, Bristol North, read a letter which was tabled.

#### APPOINTMENTS

President Ober offered the following appointments for action by the Council:

DELEGATES AND ALTERNATES TO THE HOUSE OF DELEGATES, AMERICAN MEDICAL ASSOCIATION FROM JUNE 1, 1942, TO JUNE 1, 1944:

<i>Delegates</i>	<i>Alternates</i>
David D. Scannell, Jamaica Plain	Elmer S. Bagnall, Groveland
Dwight O'Hara, Waltham	Ernest L. Hunt, Worcester
Charles E. Mongan, Somerville	Charles J. Kickham, Brookline
Walter G. Phippen, Salem	John I. B. Vail, Hyannis

DELEGATES TO THE ANNUAL MEETINGS OF THE MEDICAL SOCIETIES OF THE OTHER NEW ENGLAND STATES:

*Maine:* Warren H. Sherman, Lowell, and Carleton W. Bullard, Newburyport.

*New Hampshire:* C. Bertram Gay, Fitchburg, and John J. Curley, Leominster.

*Vermont:* George D. Henderson, Holyoke, and Wilfred A. Millet, Pittsfield.

*Rhode Island:* John A. Reese, Attleboro, and Howard P. Sawyer, Fall River.

*Connecticut:* Patrick E. Gear, Holyoke, and Wayne C. Barnes, Springfield.

DELEGATE TO THE ANNUAL CONGRESS OF THE AMERICAN MEDICAL ASSOCIATION ON MEDICAL EDUCATION AND LICENSURE AT THE PALMER HOUSE, CHICAGO, FEBRUARY 16 AND 17, 1942:

Reginald Fitz, Boston.

REPRESENTATIVES FROM THE MASSACHUSETTS MEDICAL SOCIETY TO A MEETING OF REPRESENTATIVES OF MEDICAL-SERVICE PLANS TO BE HELD IN CHICAGO, FEBRUARY 14, 1942:

James C. McCann, Worcester.

George L. Schadt, Springfield.

AD INTERIM APPOINTMENTS TO FILL VACANCIES:

Dr. Robert T. Monroe, Norfolk — chairman, Committee on Medical Education.

Dr. Chester S. Keefer, Suffolk — member, Committee on Medical Education.

Dr. James L. Chute — councilor, Barnstable.

Dr. Eliot Hubbard, Jr., — councilor, Middlesex South.

Dr. Louis F. Curran and Dr. Albert Ehrenfried — councilors, Norfolk.

Dr. William B. Castle — councilor, Suffolk.

COMMITTEE TO SELECT DIRECTOR OF THE MASSACHUSETTS MEDICAL SERVICE CORPORATION:

Peirce H. Leavitt, *Chairman*, Brockton.

Michael A. Tighe, Lowell.

Kenneth L. MacLachlan, Melrose.

William M. Collins, Lowell.

George L. Steele, Springfield.

DELEGATE AND ALTERNATE TO THE MEETING OF THE UNITED STATES PHARMACOPOEIAL CONVENTION AT CLEVELAND, OHIO, TUESDAY, APRIL 7, 1942:

Delegate: William B. Castle, Boston.

Alternate: James P. O'Hare, Boston.

REPRESENTATIVE FROM THE MASSACHUSETTS MEDICAL SOCIETY TO THE MENTAL HEALTH FOR DEFENSE ORGANIZATION, TO TAKE THE PLACE OF DR. A. WARREN STEARNS, RESIGNED:

Abraham Myerson, Brookline.

It was regularly moved and seconded that these appointments be confirmed, and it was so ordered by vote of the Council.

## NEW BUSINESS

Dr. Ober, in announcing the death of a councilor, spoke as follows:

Dr. Hugh J. Downey, a practicing physician and surgeon in Pittsfield for twenty-eight years, died on January 31 at the age of fifty-nine. Born in Adams, Dr. Downey received his degree from Loyola Medical College in 1912. Dr. Downey served as secretary of the Berkshire District Medical Society for ten years, or until 1939, when he was elected president of that district. He was an active member of the surgical staff of St. Luke's Hospital and was also a member of the House of Mercy staff. Dr. Downey was a delegate to President Hoover's Child Clinic Conference in Washington, D. C., representing Massachusetts, and to the Vermont Medical Council in 1938. He is survived by his widow, one son and one daughter.

At the request of the President, the Council stood in silence for one minute in tribute to the memory of Dr. Downey.

The President made the following announcement:

At the last meeting of the Council in October, 1941, the President and Secretary, on motion of Dr. Mongan, were directed to give their attention to the matter of the Approving Authority regulations, with a view of enlightening the Council as to the present situation. The President and Secretary have complied with this direction, and the information sought is contained in the *New England Journal of Medicine*, issue of November 13, 1941, pages 795 to 800.

The Secretary moved that the Council authorize the publication of a directory of the fellows of the Massachusetts Medical Society in 1942. The motion was seconded and so ordered by vote of the Council.

The Secretary announced that he was forced to bring to the attention of the Council an irregularity in which the censors of a district had certified a doctor in that district for membership in the Massachusetts Medical Society. This doctor had been so certified as the result of an examination which had been held on December 18, 1941. This examination should have been held on December 4, 1941. The Secretary suggested that the by-laws, as they relate to the time at which the censors' examination shall be held, be suspended in this particular case. Dr. Donald Munro, Suffolk, so moved. The motion was seconded and so ordered by vote of the Council.

Dr. Ober read a letter which he had received from Robert S. Harris of Massachusetts Institute of Technology. This letter spoke of a conference which would be conducted February 6, 1942, by the Massachusetts Committee on Public Safety on the matter of nutrition and asked that the Massachusetts Medical Society lend its name as a sponsor to this conference.

On motion of Dr. Shields Warren, Suffolk, and a second by a councilor, the Council voted to leave such matters in the hands of the President and Secretary.

Dr. Ober read a letter asking the Massachusetts Medical Society for a donation to a war fund which was being raised in Boston as a Boston activity. Dr. Ober pointed out that the Massachusetts Medical Society is a state-wide organization and, inasmuch as its members were aiding similar movements in their respective communities, he did not believe that the Society should contribute. No action was taken.

Dr. Munro addressed the Council to the effect that a doctor, who is not a member of a state or territorial medical society and who enters the Officer Corps of the United States Navy, may be commissioned an Ensign but cannot rise above that rank. He raised the question as to whether or not the Society's regulations governing admissions to membership might be waived or suspended for a period of time in the case of young doctors to whom sufficient time was not available to seek membership in the Society in the regular way.

He pointed out that the regulation which required examination of all prospective candidates by a board of censors was not merely a provision of the by-laws, but that such a requirement likewise appears in the articles under which the Massachusetts Medical Society was incorporated.

This subject provoked a great deal of discussion participated in by Dr. Munro, Dr. Homans, Dr. Halbersleben, Dr. Hornor, Dr. Mongan, Dr. Fitz, Dr. Blaisdell, Dr. Lund, Dr. Warren, Dr. Browne, Dr. Faxon and Dr. Conley.

Dr. Browne moved that the doctors described by Dr. Munro be admitted now, *de bene*, with the provision that they would later on satisfy the requirements of the Society. The motion was seconded and so ordered by vote of the Council.

Adjournment took place at 4:15 p. m.

MICHAEL A. TIGHE, *Secretary*

## APPENDIX NO. 2

## REPORT OF THE TREASURER

The treasurer has continued his investment policy, as in the past years, to protect the funds in his care, rather than, by taking greater risks, to seek larger interest returns. Hence interest income, in 1941, was moderate. From a study of investment policies of many different security portfolios, and from a study of results of many managed "investment trusts," a fair conclusion is that constant revision, vigilant supervision and wise foresight are essential in successful management of invested funds. These rules are important, as never before, when securities must be shifted promptly, as new conditions arise with startling rapidity, affecting values. Changes in the Society's investments, in 1941, have, in almost all instances, shown profits. Yet, looking ahead, the increasing threat, under war necessities, of dangerous inflation, and the deficit financing of our government for past years, are warnings to the Society, to spend thoughtfully and economically.

In 1941, Society revenues from resident dues were \$49,779. Other net revenues, from interest (not including Building Fund) \$4081; from sales, \$13; net from booths sold for annual meeting, \$1065; from nonresident dues, \$1671; from fellows in active service in Army or Navy, to receive the *Journal*, \$32; fees from examinations by censors, \$243; and finally, profits on sales of bonds, \$815;

together amount to \$7920 Hence, total revenues to the Society amount to \$57,699—the largest ever received

Building Fund received net income of \$1889, and profits from sales of securities, \$116 Both were added to the Fund which now totals \$62,075

Items of expense, in 1941, were larger, primarily because of bills for lawyers, first in connection with legislative activities, and secondly, for work in connection with the proposed Massachusetts Medical Service Corporation There are, the treasurer believes, a number of other expenses which should be reduced in 1942 As many fellows of the Society have been called to active war duties with Army or Navy, and many more must soon be called, the Society will be without their presence, their advice and their dues We should strive therefore more than ever, with conscientiousness and economy to carry on the many activities and duties, now placed on our shoulders

The Society ends 1941, with assets of cash and securities, totaling \$216,800, and unexpended revenues of over \$12,300

The treasurer takes this opportunity to thank the officers of the Society, the officers of District Societies, and, especially the office staff of the *New England Journal of Medicine*, for their continued co-operation and help

CHARLES S BUTLER, Treasurer

## APPENDIX NO 3

### REPORT OF THE EXECUTIVE COMMITTEE OF THE COUNCIL

The president of the Massachusetts Medical Society, Dr Frank R Ober, on December 7, 1941, sent a message to His Excellency, Leverett Saltonstall, Governor of Massachusetts, pledging the support of the Massachusetts Medical Society in the crisis which had arisen that day

The following letter was received from the assistant secretary to the Governor

December 17, 1941

Dr Frank R Ober, President  
Massachusetts Medical Society  
8 Fenway  
Boston, Massachusetts

Dear Dr Ober

Governor Saltonstall asked me to thank you for transmitting to him your organization's pledge of support and patriotic offer of assistance Will you please convey to the members his appreciation?

He feels that it is such spirit that will pull us through the grave struggle ahead There are many vital tasks to be accomplished involving all the ability and effort we can muster Through various channels many groups are already enlisted for specific jobs and if such is not yet the case with yours, you may be assured that the call will soon come

Sincerely yours,

RUSSELL GFOULD  
Assistant Secretary to the Governor

The Executive Committee, at its meeting December 29, 1941, approved this act of our president. I now move that this act be likewise approved by the Council of the Massachusetts Medical Society

At this same meeting the Executive Committee took notice that our country was at war This notice took the form of a resolution which the secretary of the Massachusetts Medical Society was directed to send to the President of the United States

The following telegram embodying this resolution was sent on December 30, 1941

Honorable Franklin D Roosevelt  
President of the United States  
White House  
Washington, D C

I have been directed by the Executive Committee of the Council of the Massachusetts Medical Society to submit to you the following resolution adopted in Boston, December 29, 1941

Whereas, the liberties of all peoples are seriously threatened,

Whereas, these liberties no longer exist in a large part of the world,

Whereas, contagion threatens the spiritual as well as the physical things of life,

Whereas, personal freedom, the right of free speech, the right of peaceful assembly and the right to worship God, as one's conscience dictates, comprise the American way of life, and

Whereas, the Massachusetts Medical Society has nourished this American way of life for over one hundred and fifty-eight years, therefore, be it

Resolved, that the Executive Committee of the Council of the Massachusetts Medical Society, truly representative of 5600 physicians in the State of Massachusetts, pledges its treasure, skills, loyalty and, if need be, the lives of its several members to the President of these United States and may God keep him strong

MICHAEL A TIGHE, MD, Secretary  
Massachusetts Medical Society

The following acknowledgment was received from M H McIntyre, Secretary to the President

THE WHITE HOUSE  
WASHINGTON

January 3, 1942

My dear Dr Tighe

The President has received your fine telegram embodying the resolutions adopted by your committee and he wishes me to convey his deep appreciation of the patriotic support which you so generously pledge It is extremely heartening to the President, in carrying out the will of the American people, to receive the voluntary assurances that the country stands as one man in its determination to spare no effort and to assume every sacrifice necessary to a successful outcome

Very sincerely yours,

M H MCINTYRE  
Secretary to the President

Dr Michael A Tighe, Secretary  
Massachusetts Medical Society

The Executive Committee reviewed certain reports which will be presented today under the direction of the Committee on Public Relations The first of these has to do with tax supported medical care. This report involves the adoption of certain principles which have been evolved as the result of the studies of the special committee assigned to this subject

The second concerns itself with certain recommendations six in number, which will be presented today as the result of the further efforts of the Special Committee on Prepayment Medical-Care Costs Insurance.

The Executive Committee has approved these reports and recommends them as deserving of your earnest consideration.

The Executive Committee has approved of a third matter which will be presented by the Committee on Public Relations. This has to do with an attempt to solve a vexatious matter which has arisen in certain communities out of hospital-care insurance as applied to ward patients. If the Massachusetts Medical Service Corporation is to include those who will be cared for under a similar contract covering medical-care costs, this matter must be adjusted. The Executive Committee approves the recommendations of the Committee on Public Relations looking toward this end, and urges its adoption by the Council.

The following resolution is presented for adoption by the Council:

WHEREAS, It has come to the attention of the Council of the Massachusetts Medical Society that the Social Security Department of the United States Government seems to contemplate a petition to the Congress of the United States for legislation which would extend the present social security coverage so as to include approximately 45,000,000 to 116,000,000 of the American people;

WHEREAS, It seems to be the intention of the petitioner to have included in this legislation an extension of the provisions of the present Social Security Law so as to provide for the hospitalization of approximately 45,000,000 to 116,000,000 American people;

WHEREAS, It seems to be the intent of this legislation to finance this extension, in the case of the employed, by a tax of one per cent on payrolls, one half of which is to be paid by the employer and one half as a deduction from wages;

WHEREAS, In the case of those who are self-employed, it has been intimated that it will be the intent of this legislation to finance this extension by adding to already existing income taxes an additional tax of one per cent up to an amount which will represent one per cent of \$3000;

WHEREAS, The people of these United States are now heavily burdened and will be further burdened by our war effort;

WHEREAS, This is the first step in the direction of the complete control of the care of the sick by Government; and

WHEREAS, Wherever such control has existed the quality of medical care has suffered; therefore, be it

RESOLVED, That the Council of the Massachusetts Medical Society in regular session, February 4, 1942, does hereby oppose any such extension of the present Social Security Law as is herein outlined.

MICHAEL A. TIGHE, *Secretary*

#### APPENDIX NO. 4

##### REPORT OF THE COMMITTEE ON MEMBERSHIP

The committee recommends:

1. That the following named twenty-three fellows be allowed to retire as of December 31, 1941, under the provisions of Chapter I, Section 5, of the by-laws:

Abbe, Elizabeth M., Roxbury  
Atwood, Charles A., Taunton  
Brown, Percy, Egypt  
Burton, Oscar A., Westminster, Vermont

Coffin, Arthur B., Dorchester  
Devere, Frederick H., Auburn, Rhode Island, with remission of dues for 1940 and 1941  
Everett, Frederick L., Springfield, with remission of dues for 1939, 1940 and 1941  
Grandison, Wilfred G., Charlestown  
Hamilton, Robert D., Newburyport, with remission of dues for 1940 and 1941  
Harriman, Cora E., Framingham Centre  
Holmes, May S., Orleans, with remission of dues for 1941  
McIntire, Herbert B., Cambridge  
Morrison, Robert F., Holyoke  
Myrick, Hannah G., Dorchester  
Noble, Mary G., Brookline, with remission of dues for 1940 and 1941  
Parker, Ralph W., Lowell, with remission of dues for 1940 and 1941  
Rumrill, Samuel D., St. Petersburg, Florida, with remission of dues for 1939, 1940 and 1941  
Spalding, Fred M., Boston  
Spalding, Roger, Duxbury  
Wheeler, Lucia A., Uxbridge  
White, Clifford A., Granville  
Wood, Henry A., Waltham, with remission of dues for 1941  
Wylie, Eugene C., Dorchester Centre, with remission of dues for 1939, 1940 and 1941

2. That the following named seven fellows be allowed to resign as of December 31, 1941, under the provisions of Chapter I, Section 7, of the by-laws:

Bonnar, James M., Fairmont, West Virginia  
Brown, Manning, Hopkinsville, Kentucky  
Coggeshall, Howard C., Dallas, Texas  
Prout, Curtis T., Arlington  
Ragsdale, L. V., Grand Rapids, Michigan  
Segal, Jacob A., Manchester, Connecticut  
Woodbridge, Philip D., New Haven, Connecticut

3. That the dues of the following named ten fellows be remitted under the provisions of Chapter I, Section 6, of the by-laws:

Bartlett, Bernice A., Bradford, 1939, 1940 and 1941  
Bond, Katharine E., Melrose, 1939 and 1940  
Flagg, H. Howard, Charlestown, 1942  
Kaye, Edward, Dunbar, Virginia, 1940, 1941 and 1942  
Moore, Carlton W., Liberia, Africa, 1940, 1941 and 1942  
Perrault, Gerard R., Nashua, New Hampshire, 1940 and 1941  
Ryan, James B., 1939, 1940 and 1941  
Sanders, Morris B., Unoccupied France, 1941 and 1942  
Smith, Fannie G., Malden, 1941  
Wilder, Edward W., South India, 1940, 1941 and 1942

4. That the following named thirty-three fellows be deprived of the privileges of fellowship under the provisions of Chapter I, Section 8, Clauses *a* and *b* of the by-laws:

Atkinson, Velma H., New York City  
Barnes, Louis D., Pittsfield  
Bolger, Mary E., Worcester  
Calkins, Cheney H., Springfield  
Coon, George B., Greystone Park, New Jersey  
Fraser, John A., Somerville  
Garoyan, Gaspard M., Belmont  
Hall, Charles F. A., Newburyport  
Healy, John F., Dorchester

Klapper, Claude, Staten Island, New York  
 Lane, John W., Dorchester  
 Macaulay, Joseph A., Dorchester  
 Marcellino, Samuel E., Milton  
 McCarthy, Robert J., Malden  
 McClintock, Francis B., Chelsea  
 McCready, Leo T., Jamaica Plain  
 Mintz, Samuel C., Brookline  
 Monahan, David T., Bridgeport, Connecticut  
 Northridge, Robert J., DeLand, Florida  
 Oatman, Jack G., Fort Bragg, North Carolina  
 Oberlander, Andrew J., Montpelier, Vermont  
 O'Brien, John F., Bedford  
 Peacock, George E., Tuscarora, Pennsylvania  
 Quigley, Thomas J., Boston  
 Quinby, Robert S., North Sandwich, New Hampshire  
 Roney, Hugh B., Pittsfield  
 Savignac, Eugene M., Detroit, Michigan  
 Shadman, Alonzo J., Forest Hills  
 Sullivan, Jeremiah, Fall River  
 Toohy, Thomas V., Roxbury  
 Towle, George P., Carlisle  
 Vestal, Tom F., Raleigh, North Carolina  
 Zonn, Seymour I., Naugatuck, Connecticut

5 That the following named ten fellows be allowed to change their membership from one district society to another without change of legal residence, under the provisions of Chapter III, Section 3, of the by laws

From Essex North to Norfolk  
 Lary, Alfred J., Lawrence

From Hampshire to Hampden  
 Whitcomb, Austin E., South Hadley Falls

From Middlesex South to Norfolk  
 Doherty, John L., Newton Centre

From Middlesex South to Suffolk  
 Barney, J. Dellinger, Cambridge  
 Rabinowitz, James I., Cambridge  
 Sprague, John S., Brighton

From Norfolk to Suffolk  
 Davies, John A. V., Brookline  
 Marlow, F. William, Jr., Brookline  
 Tobey, Harold G., Jamaica Plain

From Norfolk South to Middlesex South  
 McKeon, Clementine C., South Hingham

6 That the following named six fellows be recommended for readmission under the provisions of Chapter I, Section 10, of the by laws

Bassow, George W., Winchendon  
 Bianco, Harvey H., North Adams  
 Burckel, Arthur W., Adams  
 Fallon, Joseph D., Northampton  
 Hannigan, R. C., Amesbury  
 Nicol, P. H., Worcester

G COLKET CANER, *Chairman*

## APPENDIX NO 5

### REPORT OF THE COMMITTEE ON FINANCIAL PLANNING AND BUDGET

The budget this year is made in anticipation of a considerable reduction in the collection of annual dues. The

Council is aware that the dues of those fellows entering the military services will be remitted on request. Thus, if one thousand fellows enter the military services, ten thousand dollars of income may be lost. Nevertheless, your committee has held that the activities of the Society should not at present be curtailed. The situation next year will be far more clear.

Taking the items of the budget in order, as presented, the following observations are pertinent.

The reduction in the salary of the secretary, tentatively suggested by your committee last February, in view of the possible lightening of his duties through the creation of the office of Executive Secretary, was approved by you. Since then, an executive secretary has been chosen by your Executive Committee. But the lightening of the duties of the newly elected secretary has not occurred. Dr. Tighe's enthusiasm, energy and capability have led him to devote a great deal of time to his office, and the committee in charge of the budget understands that he finds the delegation of such duties as he might technically be allowed to assign to the Executive Secretary improper and not in the best interest of the Society. Therefore, your committee feels that a salary of \$3000, that paid the late secretary, is appropriate.

The salary of the Executive Secretary, as tentatively suggested and approved last year, has been adjusted in conformity with the above. Mr. Boyd, appointed by your Executive Committee, though relieved of some of his expected duties, as stated above, does, in fact, give practically his entire time to the Society, has served various committees with success and, as the Committee of Arrangements can tell you, has actually, by the development of commercial exhibits, made the Society's annual meeting decidedly profitable.

Your committee is aware that the duties of these two officers are likely to develop and change during the next few years in ways which cannot at present be foreseen. Therefore, it holds that these proposed salaries, as presented in this budget, need not be regarded as fixed precedents and should be scrutinized from time to time with a view to adjustment.

The allowance for expenses of the Society's officers is nearly unchanged. That allotted to the President and Vice President should cover, as well, the expenses of a president-elect. The sum indicated here is really a contingent fund and has seldom been used to any extent. If emergencies call for greater expenditures, the Society's by laws permit proper arrangements to be made. The Secretary's allowance is increased.

The expenditures of certain standing committees will be slightly different this year from those of last year. The Committee of Arrangements is allotted only \$100. As already explained, this committee actually makes a profit.

The Committee on Publications includes in its activities the publication of the *Journal* and the *Directory*. It has presented this year, under the system established last year, a carefully considered budget. You will notice that the *Journal*'s allotment, stationary for three years, is now actually decreased. Dr. Nye and his staff have so ably conducted their publication that its cost, per member of the Society, has been steadily lowered and its subscriptions from outsiders have been steadily increased. And though the cost of publishing the *Journal* will certainly rise next year, Dr. Nye and the Committee on Publications feel that subscriptions and advertising will cover additional expenses.

The *Directory*, may, if you so decide, be omitted this year but we call your attention to several considerations

The old directory is nearly useless; the material for the new one is ready and if not used will be wasted. If the publication is postponed a year, its expense will coincide with the biennial expense of the Committee on State and National Legislation, an undesirable event. Because of the biennial sessions of the Great and General Court, the Committee on State and National Legislation now incurs a considerable expense every other year. Last year, owing to the exceedingly long session, legal expenses were heavy. This is an off year and an allotment of only \$100 is proposed.

Among the special committees, two require consideration. The Committee on Public Relations was especially active last year over the insurance matter. The President anticipates less expense this coming year. Yet \$1000 should be made available, since some bills have necessarily hung over from last year.

The Committee to Revise the By-Laws, headed by Dr. Blaisdell, will require a considerable sum if the original plan of printing the corrected by-laws is to be carried out. But some seven hundred dollars were expended last year and Dr. Blaisdell has suggested a plan, which should satisfy the Council, by which certain changes and corrections will be printed at an expense of not over \$300, the amount recommended

The total budget is \$50,800, a sum \$1000 less than last year, and \$3500 less than two years ago.

Maternal Welfare	150
Public Relations	1000
Postgraduate Instruction	1000
Committee to Revise the By Laws	300
Tax Supported Medical Care	50
RETURNS TO DISTRICT SOCIETIES	
	4000
Total	\$50,800

APPENDIX NO. 6

REPORT OF THE COMMITTEE ON PUBLICATIONS

The Committee on Publications has secured Dr. John F. Fulton, of New Haven, Connecticut, to deliver the Shattuck Lecture during the 1942 annual meeting of the Society.

The Committee has continued to supervise the publication of the *New England Journal of Medicine*. We are extremely fortunate in having such an able editor as Dr. Robert N. Nye. Under his direction, the high quality of the *Journal* has been maintained and the circulation has continued to show a gratifying increase.

JAMES P. O'HARE  
CONRAD WESSELHOEFT  
WILLIAM B. BREED  
OLIVER COPE

APPENDIX NO. 7

REPORT OF THE COMMITTEE OF ARRANGEMENTS

At the last Council meeting, you approved the following recommendations: (1) that the annual meeting of the Council be held on the evening of May 25, 1942, and (2) that the annual meeting of the Massachusetts Medical Society be held on May 26 and 27, 1942 at the Statler Hotel, Boston. Your committee has made those arrangements. A program, detailing the various activities, will be in your hands at the proper time.

The meeting will be larger than ever, but the cost to the Society will be less than ever. It is hoped that the program will merit your approval and support.

WILLIAM T. O'HALLORAN, *Chairman*

APPENDIX NO. 8

REPORT OF THE COMMITTEE ON ETHICS AND DISCIPLINE

The committee has held three full-day meetings during the past eight months, at which many cases were discussed. These cases fall naturally into four groups:

*Group No. 1*—numerous questions submitted by fellows as to the ethical nature of proposed publications. These requests were discussed and the proposed publications read, and decisions were handed down, some for and some against, to the satisfaction of the questioners.

*Group No. 2*—complaints received against fellows for alleged advertising contrary to the Code of Ethics. The complaints comprised radio announcements, newspaper publications and, in one instance, personal solicitation. These cases were investigated, and the committee found the fellows guilty as charged. All the accused fellows acknowledged their fault, sent letters of apology to the committee and promised to desist in the future. The apologies were accepted, and the cases placed on file pending further accusations.

*Group No. 3*—numerous complaints against fellows by private individuals claiming exorbitant charges for medical services. These cases were investigated, and in each, the physician was exonerated and both parties so notified.

*Group No 4*—two complaints by fellows against fellows charging violation of Article IV of the Code of Ethics of the Massachusetts Medical Society. After numerous conversations, correspondence and thorough discussion, the committee in both instances found for the plaintiff. The defendants were so notified. Personal apologies were received in both cases, the complaints withdrawn and the cases considered closed.

Several other matters are now under investigation including two communications from the office of the American Medical Association.

## APPENDIX NO 9

### REPORT OF THE COMMITTEE ON MEDICAL EDUCATION

This committee finds its effectiveness seriously impaired by the departure of one of its members on war service. Dr John Monks left last December to enter the United States Navy. Your chairman feels that the Society owes a debt of gratitude to Dr Monks for his faithful and intelligent service. He was particularly active. He led in a study of the by laws which resulted in rephrasings that have improved their interpretation and application. He spent a great deal of time investigating the qualifications of applicants for fellowship. Also, he had begun the collection of data showing the changes that have taken place in the membership of our society in the past ten years. The material is incomplete, but he has requested that some of it be reported at this time to focus attention on certain problems that may confront us.

The membership of the Massachusetts Medical Society has grown from 4750 to 5676 in the past ten years. This is an increase of almost 20 per cent. It is a more rapid rate of increase than in previous decades. Yet the number of applicants who become fellows and are graduates of approved medical schools has fallen off sharply in the last two years. From 1932-1939, they varied from 200 to 230 annually. In 1940, they fell to 179, and in 1941, to 115. The reason for this is not clear. Perhaps the war has much to do with it. If the decline persists, it merits careful study by the Council. During this same decade, the number of graduates of unapproved domestic schools entering the Society has remained essentially unchanged—22 to 38 in each year. The number of graduates of foreign medical schools rose from 4 or 5 through 1939 to 28 in 1940 and 60 in 1941.

Perhaps a measure of the efficiency of the Committee on Medical Education would be a comparison of the number of applicants for fellowship with the number who actually become fellows, for very few whom the committee passes are rejected by the Censors. In the last four years 95 per cent, 96 per cent, 88 per cent and 89 per cent of applicants from approved medical schools became fellows. During these same years, 40, 46, 40 and 32 per cent were accepted from unapproved domestic schools, and 30, 26, 42 and 66 per cent were accepted from foreign medical schools. These figures show that considerable care is exercised by the committee.

As a result of much study and consultation with various officials of the Society, this committee has unanimously approved the sense of the following:

1 Admission to fellowship in the Massachusetts Medical Society seems to be working out more satisfactorily under the new bylaws than under the old, although it is too early to be definite on this point. Members of the committee who served under the old rules are relieved to be free of the responsibility of selecting fairly among a great number of candidates on the basis of letters and casual personal interviews. This responsibility is now delegated to officers of each district society for the relatively few applicants in their area. As they become accustomed to their duty, the committee hopes that they will come to depend upon the confidential nature of the work and upon frank and convincing characterizations of their applicants. The committee then reviews the evidence of each man and determines whether it is sufficient to accept or to reject him or whether to advise deferment. More important, the committee equalizes the treatment accorded the candidates, for it is obvious that some districts will have strict and conscientious officers and others may have more lenient officers.

2 The committee should be allowed to continue to exercise its discretion in the approval of candidates. Only in this way can similar treatment be accorded candidates all over the State, based on one set of rules interpreted in the same way in each instance. By and large, however, there have been very few cases in which the decisions of the district society officers were reversed.

3 The committee is convinced that the Council would commit a grave error if it tried to increase by law or by interpretation the length of time necessary for a reputable foreign physician to be resident in this country or in one particular community before being allowed to apply for fellowship in the Society. If the present interpretation—five years since graduation from medical school—is retained, the committee assumes the responsibility of applying the law in the best interest of the Society and in fairness to the applicants. If a more rigid interpretation is compelled, unfairness clearly will result in special instances. Such rigidity conjures up unhappy attempts to go farther and define what is meant by the practice of medicine (bacteriologists, pathologists and so forth), what is the United States (Hawaii, Porto Rico, the Philippines), and what is a community (a district society area or a town).

4 The number of poorly educated graduates of unapproved domestic medical schools who enter the Society is too great. It appears to be due in large part to the considerable efforts on the part of a few fellows to do their best for their personal friends.

ROBERT T MONROE, *Chairman*

## APPENDIX NO 10

### REPORT OF THE COMMITTEES ON PUBLIC HEALTH AND MEDICAL EDUCATION

A joint meeting of these committees was held on January 15, 1942, to consider the advisability of continuing the weekly broadcasts of the Green Lights to Health. It was brought out at this meeting that the morning quarter of an hour now allotted to this program is much less satisfactory than that in the afternoon formerly given to it, limiting the audience largely to housewives. The

station has also imposed certain restrictions on the subject matter of the broadcasts. The field of obstetrics has been ruled out, although formerly we always had one broadcast each year on this subject. No mention is permitted of any such body functions as bowel movements, menstrual periods and so forth. This has limited the scope of the talks and made them less effective.

With so many physicians entering service and with increased demands on the time of the others, the committee felt that they were not justified in calling on members of the Society to give of their time in preparing broadcasts, where it was so difficult to get definite evidence that we are accomplishing enough in health education to justify the effort. The committee voted unanimously to discontinue the broadcasts on the completion of the present program about March 1.

FRANCIS P. DENNY, *Chairman*

## APPENDIX NO. 11

### REPORT OF THE COMMITTEE ON CANCER

The *Cancer Manual for Practitioners* has met with a considerable degree of enthusiasm and copies have been purchased for distribution to the practitioners of New Hampshire and Oklahoma. Several other states are interested in it also.

The desire of the Women's Field Army to put on an intensive campaign in Massachusetts was discussed, and although the committee was sympathetic in principle to the aims of the Women's Field Army, it seemed, after careful discussion, that no change in the present situation was warranted, and that the Society should not be asked to support a campaign by the Women's Field Army at the present time.

The matter of the reportability of cancer cases was discussed. It was felt that it would provide interesting and somewhat useful data. However, the committee feels that compulsory reporting of cancer cases is not advisable because of the opposition of patients and the fact that reporting must be by name to avoid duplication. In addition, it must be remembered that the reporting of diseases is an integral part of the police power of the Department of Public Health and, as such, should be restricted to those diseases dangerous to public health. Reporting of cancer morbidity was attempted by New Hampshire, found unworkable and abandoned.

The excellent work of the state-aided cancer clinics throughout the Commonwealth is known to the majority of practitioners. These clinics have been established with the active co-operation of the practitioners in a given community and serve as striking examples of how enthusiastic co-operation between the medical profession and the public-health authorities may react to the great benefit of patients. The Massachusetts system has aroused great interest in other parts of the country, and the Massachusetts cancer program is regarded as the most satisfactorily functioning program now in operation.

In view of the fact that the Society has a very real interest in these cancer clinics, and in view of the fact that such a move would be welcomed by the public-health authorities, it is recommended that a representative of the Society, preferably a member of the Cancer Committee, be appointed by the President to visit the various

state-aided cancer clinics and report to the Society on their present state.

F. G. BALCH  
E. M. DALAND  
C. C. SIMMONS  
P. E. TRUESDALE  
SHIELDS WARREN, *Chairman*

## APPENDIX NO. 12A

### REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

1. The committee has given preliminary consideration to a "postpayment" plan for medical care sponsored by the banks and now utilized by the Massachusetts Dental Society. We recommend that the President be authorized to appoint a committee of three from the Massachusetts Medical Society to confer with the bank committee about this plan and report to the Council through the Committee on Public Relations.

2. The Committee on Tax-Supported Medical Care has formulated a set of principles and proposals. These have been carefully considered by the Committee on Public Relations and we now recommend their adoption. You have received printed copies of this report. If the Council adopts these as its policy, they will be submitted to organized welfare associations for concurrent action. After this is accomplished, the material will go to the local administrators of public medical care. The district medical societies have already been urged by this council to have their committees on public relation or a special committee apply and maintain steady but judicious pressure for better conditions and standards of public medical care.

3. We believe that insurance cases (Blue Cross, Workmen's Compensation cases, automobile accidents and prepayment medical-costs insurance) should be admitted to hospitals in the care of their physician of choice. About half the hospitals of this state now provide this "private ward" privilege. The practice is almost universal outside the Atlantic Coast states. We recommend that the Council instruct the Committee on Relations with the Massachusetts Hospital Association (Dr. Clute, chairman) to see whether there can be agreement on a state-wide policy in this matter.

4. The Committee on Public Relations has given major consideration to the setting up of the Massachusetts Medical Service Corporation. We feel that the Society is fortunate in having available for these studies James C. McCann, who combines capacity and the service motive to an unusual degree. He will present the report of the McCann Committee as adopted by the Committee on Public Relations.

E. S. BAGNALL, *Secretary*

## APPENDIX 12B

### REPORT OF SPECIAL COMMITTEE ON PREPAYMENT MEDICAL-CARE COSTS INSURANCE

Governor Saltonstall, on May 22, 1941, affixed his signature to an enabling act, which became a law of the Commonwealth, empowering the Massachusetts Medical Society to establish a nonprofit corporation for prepaid

medical care costs insurance. Basic principles incorporated in the act provided (1) for preservation of the traditional patient-physician relation which guarantees free choice of physician to the patient, and freedom of action with the proper restrictions of licensure, law and ethics, to the physician, (2) for participation in the program by all duly licensed physicians in the Commonwealth (3) for subscriber representation in the corporation by virtue of the quasi public character of the corporation and in recognition of a legitimate subscriber interest in such a program, (4) for supervision of the corporation by the Commissioner of Insurance so that the profession might properly discharge its serious moral obligation to conserve and protect potentially large accumulations of prepaid funds collected from the public.

In October, 1941, the Council voted approval of by laws which outlined a corporation devised to carry out the meaning of the enabling act, and to ensure fair and reasonable controls over the actions of the corporation in medical matters by the medical society which was to create and finance the corporation, and which was contributing the support of its membership to achieve its ends. These ends are to help alleviate the burdensome costs of medical care for the low income group, and to avert the threat of compulsory health insurance, or of compulsory reorganization of the medical profession into groups under lay or political domination.

Today, in February, 1942, the Council is requested to take definitive action on proposals, the acceptance of which will place us much nearer the achievement of our goal. We present these proposals at a time when the satisfactory financial condition of the Commonwealth will assure interest in our program by industry, trade and labor. We present it at a time when activities in Washington indicate that reformers again seek to inject government controls into the problem of medical care. Consider the announced program of nine points of freedom for the post war world, which, in article three, calls for adequate food, clothing, shelter and medical care, consider the annual message on the state of the Nation, calling for extension of hospitalization benefits to the unemployed, consider the proposal of the Social Security group that cash benefits and hospital expense funds be extended to all groups of the population while ill and unemployed, on the basis of extended taxation, consider that all such proposals are initiated and pressed by Falk and Altmeier of the Social Security Department, both public advocates of and propagandists for compulsory health insurance. Well may the profession be on the alert lest we suffer a Pearl Harbor in medicine, when our membership is deployed whilst giving unselfish service in the armed forces for defense of precious liberties which some within our very borders would abridge.

#### GENERAL OUTLINE OF PROPOSALS FOR EFFECTING INCORPORATION

Turning to the specific proposals on today's agenda, they seek to attain three objectives. The first group of proposals relate to several incidental measures necessary to complete the establishment of our corporation. These steps are as follows: co-ordination of our activities with the Associated Hospital Service group (Blue Cross), appointment of a special committee to select an executive director, authorization for procuring the services of an attorney for the special committee, and appropriation of \$75,000 as required by the Commissioner of Insurance. The second proposal relates to determination of income levels of eligibility for participation as a subscriber in the program. The third proposal seeks approval of the principle that complete medical coverage shall be gradually

approached through well defined steps of partial coverage. It would be trite to recall to this council that our last proposal of partial coverage as an initial step, asks for reversal of previous decisions made by this body. But it is well at this juncture for us to recall that the impact of world crisis has been adequate cause for the Supreme Court of our land to reverse previous decisions. I have no fear that the Council of the Massachusetts Medical Society will find itself so hidebound by previous decisions as to hesitate at reconsidering them in the light of new data and figures. I am confident that the Council will look to the cold logic of facts and experience for guidance, and that it will be influenced more by solid authority on what actually has been than by vapid theorizing on what might be.

#### PROPOSAL RELATIVE TO INCOME LIMITS OF ELIGIBILITY

The proposal relative to income limits of eligibility presents a fundamental and difficult problem. The proposal reads: That income levels for eligibility for medical service contracts (contrasted to medical indemnity contracts) be set at \$2000 for an individual and \$2500 for a family, estimated as average family income. At present only medical indemnity and not medical service contracts shall be offered above these levels.

First, we must have clearly in mind what we mean by the terms medical service contracts and medical indemnity contracts as relating to this proposal. We must once and for all eschew academic and pointless discussion relative to this distinction, and all futile argument as to whether or not this constitutes insurance. We must relate these two terms, for clarity's sake, to the practices we intend to carry out. Let us consequently discuss the practices and not sterile terminology. By medical service contract, we mean the practice of making available to subscribers, within predetermined income limits, contracts with the corporation on the basis of which they shall receive needed medical services of the types and amount designated in their contract, from a participating physician of their own choice, and that having received such medical services, the subscriber shall have no additional charges made to him by the physician other than such coinsurance or initial charges as are specifically enumerated in the policy—the physician in the transaction being compensated directly by the corporation on a unit basis related to an established fee schedule. The medical indemnity contract, on the other hand, indicates the practice of selling contracts by the corporation to those people with incomes above the designated level, who wish to avail themselves of some protection against the cost of illness. For the services enumerated in their contracts, the physician rendering service shall receive a specified amount from the corporation, this amount standing as a credit on the full charge presented by the physician who has in no way bound himself concerning treatment or charge by contract with this upper income group. The total charge by the physician for service to a subscriber in this category remains on a personal contractual basis between the patient and physician as it does at present. The subscriber stands personally responsible for the payment of the difference between the charge by the physician and the allowance by the corporation.

This brings us to the difficult problem of establishing specific income levels to which the two types of contracts shall be related. We must base our decisions in this matter on several interrelated factors. These factors may be identified as the general economic background of and wage levels in Massachusetts and those factors that have influenced previous decisions reached by ex-

isting medical-service plans under medical auspices in other states.

With reference to the first factor,—the economic background of Massachusetts,—the individual members of the Council have previously received a brochure entitled, "The Economic Basis for Prepaid Medical-Care Costs Insurance in Massachusetts." As the brochure was prepared hastily for the use of the special committee, there are a few basic charts which have since been more accurately calculated, and these will now be presented.

An adequate conception of the economic picture of the State is essential if we are to embark on an economic experiment of this magnitude on a state-wide basis. Otherwise serious misjudgments may be formed or ill-conceived actions taken. Massachusetts is basically an industrial state, with urban concentration of the population (Table 1). The census figures for 1940 indicate that the

TABLE 1. Percentage Distribution of Urban and Rural Population in Massachusetts (1940 Census).

REGION	1940	1930	1920
	%	%	%
Urban .....	86.1	90.2	94.8
Rural .....	13.9	9.8	5.2
Rural farm .....	2.9	1.9	1.6

distribution of the population is 86.1 per cent urban and 13.9 per cent rural. Of the latter group, only 2.9 per cent is bona fide rural farm settlement. Also an analysis of the occupational distribution of the population as wage earners may be had from a compilation based on the report of gainfully employed persons in the census of 1940 (Table 2). This chart was prepared by Mr. Joseph F.

TABLE 2. Occupational Distribution of Gainfully Employed Persons in Massachusetts (1939).

\*Agriculture, professional, domestic, clerical, self-employed, federal and all other unclassified groups.

King, the statistician for the Department of Labor and Industry. As indicated by the chart, the group employed in industry represents between 30 and 40 per cent of the whole body of gainfully employed workers in the State. The percentage levels fluctuate from low to high, depending on the index of industrial production, at any given time. This, in turn, is influenced by such factors as depression, strike, lay-off, high or low investment, and, as at present related to the war, boom and depression. The next significant large employed group, but is approximately only half the size of the group, is the body of trade employees. This constitutes roughly 20 per cent of the wage earners

next several groups characterized by such activities as public utilities, state, county and municipal employees, teachers, services and construction encompass about 20 per cent of the wage earners, although each individually accounts for not more than 3 to 6 per cent of the gainfully employed persons. There is one very large unorganized group—the 19 per cent of unskilled workers—who will be difficult to reach with a program. These figures indicate immediately that the tactical approach must be toward the industrial groups, and toward such large single units as lesser classifications. With evolution of the present actuarial methods should be developed for the lesser classifications down to the ultimate of the individual. It is basic, however, that the smaller units are wholly desirable from an enrollment and percentage enrollment of the personnel is that this constitutes the safest form of actuarial method as far as distributing risk and diluting it against the corporation are concerned. Moreover, a 60 per cent enrollment in their individual units.

It is important to analyze the industrial units from the angle of size and geographic distribution of industrial units (Table 3). A fundamental fact is that of the 9007 industrial units in the state in 1941, only 900, or 10 per cent, are large (each employing 100 or more workers) and 75 per cent of the approximately 500,000 wage earners in the State. The remaining 85 per cent of the units are small (each employing less than 100 workers) that account for only 25 per cent of the wage earners. Our problem thus becomes one of numerical basis, the industrial groups being the objective, the trade groups our secondary objective, the other business classifications our tertiary objective. In the industrial group we must secure the co-operation of the large industrial units. The objective must rest on a factual basis, the location of these primary units. 8.5 per cent are located in the city of Metropolitan Boston, and 7 per cent of the remainder of Massachusetts. This distribution or localization of the geographic distribution of the wage earners themselves (Table 4). 19 per cent of them, and in the city of Boston) account for 67 per cent of the wage earners, — as against 14 per cent of the total. A secondary breakdown of the Metropolitan Boston area shows that industrial wage earners in Massachusetts accounts for 10 per cent of the total, but that the two cities of Boston account for 10,000 more than the city of Boston. The large group of industrial units is one of making an analysis from the viewpoint of the wage earners and physical location of industrial communities. What then, in the significance of the industrial units in the metropolitan area is the predominant factor in the cities of the metropolitan area.

h two thirds of the trade employees in the State Metropolitan Boston, according to Prof Richard P Doherty, of Boston University College of Business Administration, has a density of retail trade which is the highest in the Nation, being greater than that of New York City and that of thirty six states. The problem is thus further clarified. The wage earners in the heaviest employment category (the large industrial units outside Metropolitan Boston), the employees in the second employment category (the large trade units in Metropolitan Boston) and the workers in the

highest wage level as of September, 1941, was in the construction business (\$37 07 per week), and the lowest was in the retail trade group (\$22 11 per week). Other groups ranged between these levels. As strikingly different experiences in the weekly wage levels occur over a period of years as between the two major groups—industry and trade. The trade workers earned an average weekly wage of \$21 48 in 1939, as against \$23 75 in 1941, the industrial wage earner averaged a weekly wage of \$21 65 in 1939, as against \$30 62 in 1941. Thus the earnings of the trade

large units of the third general employment category (the diversified classification) must be successfully attracted to enroll in any program for prepaid medical care. Without the support of these economic groups, and the support of a large segment of the medical profession of Massachusetts, any prepaid medical-care program is foredoomed to ignominious failure.

No definitive action on this problem of establishing income limits of eligibility should be taken until we couple the preceding analysis of economic establishments and

the distribution of wage earners with a factual investigation of the annual earned wages of gainfully employed persons in Massachusetts. There is of course as wide a variation over several years in the wage levels, as there is in employment (Fig 1). In recent years the index number of wages has risen from the low figure of 58 in 1939 to the figure of 115 at the close of 1941. There is likewise a wide range in the wage levels in different occupational groups as of any given date (Table 6). The

worker tend to be stabilized at a median level during all phases of a business cycle, while the earnings of the industrial wage earner fluctuate widely over the cycle from a low of approximately the same median level to a decidedly higher level. The fluctuations in industrial wage pay are based not only on the rate of hourly wage, but also on the hours of employment. The recent increase of 40 per cent in the industrial wage level is due largely to overtime employment and overtime pay. Strangely this increase has been accompanied by an increase of only 65 per cent in the number of employed wage earners in industry.

A pertinent analysis of the specific annual earnings of workers in Massachusetts is available in a modified study by the Massachusetts Division of Employment Security, prepared by the Department of Research and Statistics. The basic chart has been modified with the help of Mr

Joseph F King to suit the purposes of this study (Tables 7 and 8). Our deep obligation to Mr King for his valuable and generous contribution of time in this work should be recorded here. Table 7 is based on a statistical sampling of earnings reports as taken from the files in the Division

of Unemployment Security for 1939. The original figures were based on a sample of 30,525 reports. The groups earning from \$70 to \$400 a year were excluded from the revised chart here used, as they are constituted presumably of schoolboys, students in part-time employment, and

achievement of secure footing, these limits might properly be extended. Table 8 indicates that these figures apply to a group of wage earners of whom 95 per cent are employed throughout three or four of the quarters of the year. The importance of establishing the second or family

*This chart verifies the present high level of wages; the 1938 and 1939 levels are about normal.*

individuals with odd-time occupations who are not themselves interested in or capable of carrying full-time employment. The exclusion of these groups, which are not pertinent to our study, brings the sample down to 20,877, as shown in the table. The first eight blocks comprising the groups with earnings from \$400 to \$800 annually have, by action of the Wage-Hour Law enacted since the original study was made, been moved up into the group earning \$750 to \$800 annually. Such is the connotation of the word "corrected." The study shows that 25.7 per cent of a diversified group of wage earners in

level of eligibility is indicated by Table 9 which represents the experience of Blue Cross enrollment. Nearly half the semiprivate subscribers (48.1 per cent) and nearly three fourths of the ward subscribers (71.9 per cent) purchase hospital insurance contracts on a family basis, rather than on the basis of a smaller unit. A comparable

TABLE 6. *Analysis of Employment and Earnings in Massachusetts (September, 1941).*

GROUP	NO. OF WAGE EARNERS	TOTAL WAGES	AVERAGE WEEKLY WAGE
Manufacturing	459,580	\$13,966,299	\$30.39
Retail trade	73,445	1,624,102	22.11
Public utilities	48,455	1,744,871	36.01
Municipal employment	19,887	549,060	27.05
Wholesale trade	18,305	572,799	31.28

Massachusetts earned in 1939, \$750 to \$800 per year and that 14.9 per cent received \$800 to \$1000 per year. It is seen that 22.8 per cent received \$1000 to \$1500 per year; and that 20 per cent received from \$1500 to \$2000 a year. Thus it may be summarized that approximately 40 per cent of the wage earners receive from \$750 to \$1000 a year; that another 40 per cent receive from \$1000 to \$2000 a year, and that, of the remaining 20 per cent, a little less than 10 per cent (8 per cent) earn from \$2000 to \$2500 per year. If the income of the wage earners is taken as representing the total family income, then the proposed income level for eligibility of \$2000 for the individual (83.4 per cent of the wage-earning group) and \$2500 for the family (91.4 per cent of the wage-earning group) fairly discharges our responsibility to the low-income wage earner of the State in the initial stage of an experiment having potential magnitude of significant proportions. Interestingly, the comparable industrial state of Michigan adopted similar levels of eligibility, encompassing in Michigan 87 per cent of the workers at \$2000 and 93 per cent at \$2500. With the passage of time and the

experience might reasonably be anticipated among subscribers to medical-care insurance.

There are other factors which should be properly evaluated in arriving at a decision on this matter of income level of eligibility. They are quickly brought into focus by authoritative statements from other states which have

resolved this problem. There is shown in the second column of Table 10, the variations in the income limits of eligibility established by various states which have embarked on medical-care programs. In every state group,

gical Care, Incorporated, of Utica, New York, has established itself on this basis. All other major groups have elected to establish income levels of eligibility. New Jer

*Michigan Medical Service.* "The income limits for eligibility were chosen on the basis of a number of income studies which indicated the level of \$2000 for the individual and \$2500 for the family constituted the so-called 'comfort level' above which persons were able to make individual arrangements for medical charges. The limits were also approximately (slightly lower) the limit of \$3000 proposed in government legislation for the under-income group." Laux, J. D., *Executive Director.*

*California Physicians Service.* "In arriving at the income level of eligibility, there was naturally a great variety of opinions as to how high or low it should be. The one factor that perhaps had the greatest influence was the family net income provision in the bill that was at that time being strongly pushed in the legislature. This bill provided for compulsory health insurance for all people earning up to \$3000, therefore this base figure was used in the rules of California Physicians Service." Nelson, J. Philo, *General Manager.*

*Western New York Medical Plan (Buffalo).* "In regard to the factors which influence the individual and family eligibility, would say that during the period of organization of the plan, there were two groups who held diverse opinions on this question. First, the majority opinion was that the income limits, or ceiling, should be very low. The minority view was that we should have no limits at all. The majority opinion prevailed, and the limits were set at \$1500, \$2000 and

sey Medical Service established a low level of \$1600, but for reasons unknown to the committee changed the limits to \$2000 for the individual, \$2500 for man and wife, and an allowance of \$200 for each child up to the income limit of \$3000. How the other major groups arrived at their figures is indicated by the following extracts from correspondence with them:

\$2500, respectively, for the three classes of subscribers — individual, man and wife, and family. When this plan was presented to the Insurance Department of the State, they demurred on the grounds that the limits were entirely too low, and at their insistence, they were raised to the present limits of \$1800, \$2500 and \$3000." Critchlow, George R., *Medical Director.*

There are further reasons why the committee suggests this simple approach on the basis of a flat level of individual and family incomes. The personnel managers of many organizations were polled and the opinion held by the majority of them indicated that their co-operation would be procured only to the extent that the society presented a simple basis of income eligibility for enrollment. Several organizations would refuse to divulge differing income levels among their employees; others would not set up the machinery for determining complicated and varying income bases for eligibility. If this responsibility devolved on the medical-service corporation, it would entail increased administrative expense. Industrial surgeons engaged in offhand conversation and queried, "What income limits encompass our problem?" replied, "About \$2000 to \$2500 for the family."

Proceeding on this simple base for enrollment, we can transpose the whole problem into an actuarial one, rather than establishing it on a complicated, unwieldy and poorly controlled enrollment basis. Because of these empirical reasons and the preceding statistical data, the committee has seen fit to recommend the same income levels of eligibility (or ceiling) as the comparable industrial state of Michigan, that is, \$2000 for the individual and \$2500 for the family, estimated as average family income. Above these income levels or ceilings, contracts will be available for the present only on a medical-indemnity basis.

#### PROPOSAL RELATIVE TO PARTIAL-COVERAGE OR COMPLETE-COVERAGE CONTRACTS

The next proposal entails complete reconsideration of all previous actions taken by the Council relative to the method of approach to the problem of prepaid medical care. The proposal reads, "That contracts be prepared and presented on the following basis: (1) the quick presentation of a so-called 'surgical contract' (coverage for the expense of hospital surgery, obstetrics and diagnostic x-ray service); (2) preparation, as quickly thereafter as is feasible, of a total hospital medical-care contract to cover all medical fields incidental to hospital medical-care expense; and (3) the careful, slow preparation of a comprehensive medical-care contract covering medical-care expense in the home, office and hospital, to be presented later."

Your committee urges a gradual approach to our ultimate objective and ideal—total medical-care coverage by a comprehensive policy—through well-defined initial steps of partial coverage. There are many reasons for not initiating our program with complete coverage, all of which may be summarized briefly as follows: complete medical-care coverage as the initial step in an extensive program has proved hazardous and frequently unsound; it has lacked widespread public acceptance by the low-income groups, the one true measure of public demand and interest; it has been subject to disrupting and ill-controlled abuses by the public in medical care at the office and home; and it has entailed either serious financial loss or inadequate compensation for the physician when unbuttressed by surpluses from more actuarially sound partial-coverage contracts.

It is well to realize that with the years of experimentation behind the profession, in which most initial ventures in other states were initiated with complete medical-care contracts, a survey of the breadth and length of this mighty land reveals only about 300,000 subscribers (exclusive of 450,000 in Michigan) to medical-care programs. Such a result will neither solve the problem of medical

costs for the low-income group, nor roll back the threatening wave of government control of private-family medical practice. The experiments have been of inestimable value as a source of information for developing sound, widespread, and publicly acceptable programs. However it seems that failure to proceed successfully at a faster pace in the future will prove futile and disastrous. Reformers wait neither on time nor doctors! This recommendation for initial partial-coverage contracts mirrors the findings of an earlier committee, the Subcommittee on Social Legislation Insurance of the Committee on Public Relations, which in 1938 recommended partial coverage for medical expense in the hospital only. Your present committee in effect resubmits its sound conclusions, following a survey of recorded experiences during the past five years in various sections of the country, and it furthermore presents support for such an initial partial-coverage step, by way of recommendations from outstanding authorities in the field.

Why should we consider charting a new course and rejecting total coverage as the initial step? The reason comes persuasively from the lips of Mr. John R. Mannix, who years ago was active with the Cleveland Academy of Medicine in formulating its plans, and is now director of Michigan Hospital Service and interlocked actively in administrative work with Michigan Medical Service. He writes:

The public is not yet ready to accept prepayment for complete medical care. The first prepayment plan was for hospital coverage in New Orleans, St. Paul and elsewhere in 1933. The movement started by offering hospitalization at 60 to 80 cents a month for the individual. The public took the attitude that there was not much to lose. Then the call on the budget was slowly increased to \$1.50 or \$2.00 a month for the entire family in 1936. When the Michigan medical-care plan for complete coverage was started, this meant a jump from \$1.50 per month for family hospital coverage to \$6.00 per month for family coverage of hospital and complete medical-care expense. The public is not ready to budget that much money. They must be led gradually to increasing budget contributions. The only ones who took the complete medical-care program were large numbers of people in groups which were known to need considerable medical care. Thus groups were selecting adversely against the program. As a consequence the complete medical-care portion of the program suffered a deficit of \$75,000.

It should be recorded here that it is Mr. Mannix's conviction that over the years the American people can be educated through the medium of partial-coverage contracts to budget the sums necessary for complete medical-care coverage.

Experiments with prepaid medical-care programs fairly well cover the Nation. When Massachusetts, venturing on a state-wide program, looks abroad to profit from experience elsewhere, she must use discrimination regarding sources whence conclusions are drawn. We have nothing to learn from a chain of small private group-clinics like the Ross-Loos organization in Los Angeles. Having rejected the basic philosophy of consumer dominated co-operatives in the field of medical care, there is but little to learn from the Elk City Medical Cooperative, of Oklahoma, in the heart of a producer and consumer farming co-operative country, or from the federally financed and nurtured Group Health Co-operative in Washington, D. C. Small medical plans in individual cities and in restricted geographic sections afford little dependable ex-

perience for such a venture as Massachusetts approaches. We must be particularly wary of the dependability of the many general surveys stimulated by the report of the Committee on the Costs of Medical Care (1928-1931). Many of these surveys seem to assume an unwarranted degree of accuracy. Michigan found that a survey estimate of eight hundred office calls per 1000 subscribers grew to the figure of three hundred office calls per 1000 in actual field experience and that the United States Public Health Survey estimate of a case rate of one mastoid and one hernia per 1000 persons per year, proved from field experience in Michigan to be two mastoids and four hernias per 1000 per year. Accepting the integrity of the bulk of the profession as a basic premise, we had better interpret this discrepancy as incidence of the absolutely restricted value of general surveys, rather than as evidence of unnecessary surgery. People are not fooled about mastoids or hernias at the rate of two to one and four to one. This may properly be interpreted as more adequate distribution of needed surgical care. The most valuable lessons for Massachusetts are to be derived from the states of Michigan, California and northern New York.

Having reviewed the empirical conclusions of Mr. Mannix, let us review his story of Michigan's actual experience with a complete medical-care contract. He writes:

The Michigan Medical Society and its Board of Delegates originally proposed and developed a program for complete medical care. The Ford Motor Company became interested as the first large subscriber but would not permit a deduction of \$6 per month for complete coverage of hospital and medical care for the family. They said they would only take surgical care. Such a contract had not been prepared or planned, and the Medical Society at first opposed partial coverage. Because of the insistence by industry, they then agreed to prepare a policy offering surgical, obstetrical and x-ray coverage, with the understanding that they would push the complete medical care policy and offer the partial coverage only where it was demanded. But they found that the public was not ready for an adjustment from \$150 for monthly family hospital coverage to \$6 a month for total family hospital and complete medical coverage. Despite all efforts, they could not get any interest in complete medical coverage even when they pushed it. At first they even had no folders on surgical coverage. But industry kept insisting. Why not talk about surgical coverage? In practice they have had to reduce complete medical-care coverage because of the abuse it was subject to. The abuse was in the home and office visits. The chief ones were in allergy and in pediatrics. A mother would come downtown with five healthy children and walk in on the pediatrician for examinations. The physician in this policy became as available as the nearest telephone. The Michigan Medical Society has lost \$75,000 on the complete medical-coverage plan, even though they had a deductible initial charge of \$5 which the patient paid.

Further evidence of the unsatisfactory Michigan experience with complete coverage is attested by the statement of Mr. Begley, assistant director of Michigan Hospital Service at a meeting of those interested in the medical plans in Atlantic City on September 16, 1941. He said:

They enrolled the entire Highway Department of the State of Michigan under a complete medical program, after a year's experience, the plan lost approximately \$10,000 on this one account. It had been determined that subscribers would use approximately eight hundred

office calls per one thousand subscribers, but in this one case subscribers used sixteen hundred office calls per 1000. The Michigan Medical Care Plan was not as successful as they had hoped.

In view of these enlightening revelations, how has Michigan Medical Service achieved its phenomenal success of over 400,000 subscribers, and participation by Michigan physicians to the extent of over 80 per cent in one year? They did this by responding realistically to the public demand in industrial Michigan with a partial coverage contract for surgery, obstetrics and x-ray service in the hospital. The public emphatically demonstrated their interest when at one period in the first year, it had bought over 187,000 surgical contracts and only 5816 complete-coverage medical contracts. Later in the year, General Motors participated in the plan to the extent of enrolling 250,000 subscribers. 82 per cent of these bought the partial-coverage surgical policies. On this contract, Michigan Medical Service has paid 100 cents on the dollar of the established fee schedule on the complete coverage contract. It has paid 70 to 85 cents on the dollar, but with a substantial deficit. During 1940, \$200,000 was paid to the physicians for services to subscribers. During 1941 over \$1,000,000 was paid, and at the present time payments to physicians approximate \$200,000 per month.

One matter of major importance from the viewpoint of our secondary objective of blocking compulsory health insurance is the rapid rate of enrollment in Michigan in one year (400,000 participants) in comparison with the 300,000 enrollees in all the other plans in the country over a period of years. Michigan has also dealt with one of the most strongly organized groups of union members in the country. In striking contrast with the demand of many labor leaders for compulsory health insurance, there stands the attested attitude of the individual members of the United Automobile Workers in Michigan that they sympathize with the doctors not wanting government in medicine and in the hospitals just as they themselves want to keep government out of the unions, and that so long as the physicians continue to provide a satisfactory arrangement for them for medical care, that will continue to be their attitude. Bearing out the achievement of Michigan Medical Service in reaching the low income groups which are not so effectively organized in unions as the automobile workers, is the fact that the best enrollment has been among the distinctly low income group. Kresge store girls get \$13.00 per week, and 92 per cent of these girls in the Kresge stores in Michigan are enrolled and there are 2000 of them. Mr. Mannix has the following to say concerning these girls:

They are self-respecting; they buy everything else, and they consider these rates within reason. The reason they previously went to the hospital as charity ward service cases was not that medical care was so expensive; they were not prepared to budget for the expense. There are relatively few families who cannot budget for medical care.

Further valuable information concerning experience derived from an extensive geographic area is available from California. In view of the gratuitous remark so frequently passed, that a complete medical-care program with an initial enrollment of 5000 to 10,000 people can successfully carry itself and properly compensate the physicians, the California experience with 30,000 subscribers is particularly enlightening. Mr. Mannix, of Michigan, reports

California offered complete medical-care contracts only, from 1939 onward for two years. After two years' experience with the complete medical-care contract, they were convinced that the complete program was not what the public wanted. Their monthly rates were \$4.50 for man and wife and two children and \$0.75 for every other child. Their complete contract was thus less expensive than Michigan's. With it they paid the doctors an average of 60c on the dollar. After two years they visited Michigan to get information about the surgical contract. Last August, they offered the surgical contract to the public.

Direct correspondence with the administrators of the California Physicians Service expands the basis for these assertions. A letter from Dr. Larsen, the secretary and medical director, contains the following illuminating remarks:

The trick in all of these medical plans is to get off on the right foot. Once you are in the game it is very hard to change around, and while you are doing so you lose both medical and public support. I am just throwing this out because I feel that this is the proper way to approach the development of a medical-service plan. . . .

There is no question but what the public *wants* full-coverage medical service rather than just the surgical benefit. Our figures to date . . . involving over 30,000 members . . . would lead us to believe that *the public is not yet prepared to pay the cost* that a full-coverage plan would require. We have gone into the full-coverage with complete knowledge of this, but we felt that some of these medical-service plans should find out just what the implications of full coverage under the free-choice service would actually mean in terms of dues and in terms of public reception. We believe that we are pretty close to the answer after two and one half years of experience. We have found that the full-coverage plan puts us into the white-collar class and does not get us the real low-income people. This has made for bad public relations as far as the medical profession is concerned, because a good number of our physicians feel that these people have been able to pay their bills previously. When you are confronted with a low-unit value, the doctor feels that he is losing money by taking care of this class of people.

A final statement with reference to the weakness of complete coverage as an initial approach for Massachusetts is contained in a letter, dated December 30, 1941, from J. Philo Nelson, general manager of California Physicians Service:

Experience under the full-coverage medical contract, in which all services, including the first visit, are taken care of, indicates a considerable amount of abuse on small insignificant ailments. This abuse is enough to have a definite influence on the payments that can be made for all services under the plan. California Physicians Service has now discontinued the sale of this particular contract, and in lieu thereof is offering a contract in which the member patient must pay for the first two visits in each ailment. Whether or not this restriction can solve the problem we shall not know until we have sufficient experience.

The questions now arise, Are we to profit by the experience of these existing medical plans, or are we going to blind our eyes to the very evident implication of

these results, and have to relearn the same costly lessons which these planners have concretely revealed? All of us who follow their lead are profoundly indebted to the physicians and lay associates in the various sections who have sacrificed time, effort and income that we who now must run, may profit by their more leisurely experience. Three striking facts are apparent from a survey of the field: most plans which started initially with a complete-coverage medical contract have been forced by public demand to fortify it with a partial-coverage contract; there is about an even division among these plans (Table 10) concerning which of two types of partial coverage is best added to the complete-coverage contract, that is, a hospital surgical, obstetrical and x-ray partial-coverage contract or a partial-coverage contract providing for all medical-care expense in the hospital; and there is definite feeling among these now experienced administrators that a state program, newly starting, might be well advised to initiate its program with a partial-coverage contract.

The opinion and the recommendation of your committee are that, profiting by these valuable experiments elsewhere, Massachusetts Medical Service be initiated on the basis of a partial-coverage contract. Our two objectives might be set as follows: to demonstrate to the many states that are becoming interested in voluntary prepaid medical-care programs and, like us, must profit from the experience of those that preceded us, how quickly and solvently such a program may be established on a state-wide basis; and to measure empirically the degree and extent of medical coverage and the premiums which the public will accept at present, and, as a corollary, the rate at which the public can be led voluntarily through partial coverage, to budget for complete medical-care coverage. The profession should not police the public to acceptance of specific types of medical coverage, any more than the government should. To this end your committee has recommended the immediate presentation of a partial-coverage contract providing for hospital surgical, obstetric and diagnostic x-ray benefits. This policy is actuarially sound; it represents the present limit to which the public gives evidence of participating voluntarily in large numbers; it will establish the corporation on a sound basis and create a reserve to buttress a more experimental total-coverage contract later. Within a short period of time after presenting the surgical contract, a contract covering complete medical-care costs in the hospital would be presented. This second policy would thus cover all the catastrophic medical expenses incidental to hospitalization. Then over a period of one or two years, a comprehensive medical-care contract covering medical-care expense in the home, office and hospital can be prepared, based on a further experience with this contract in other sections, and buttressed by a financial reserve accumulated with the actuarially sounder partial-coverage policies. The present committee would not assume the responsibility of preparing and presenting a complete-coverage policy within a shorter period of time than one or two years. As the committee senses a determination on the part of the Society to act immediately, there seems no rational alternative but to initiate the program on the basis of a partial-coverage contract.

The lessons of experience point this way as indicated by even a cursory examination. Conviction comes more completely by specifically seeking advice from unquestioned authorities on medical-care programs. The following excerpts from conversations or correspondence with such authorities leave little doubt as to the logic

of an approach through partial coverage for any statewide plan initiated from this time forward. Again I quote from Mr. Nelson, of California Physicians Service, who writes, "The surgical benefit contract is more or less predictable from an actuarial basis, and is the soundest one to begin with." This viewpoint is emphatically substantiated by a frank categorical statement by Mr. Mannix, 'From the experience of Michigan, partial coverage is the only approach that is reasonable.' He continued in an advisory tone that the recommendations of our committee were sound and that 'it would be well to go to the combination of hospital coverage with surgery, obstetrics and diagnostic x-ray, then to hospital coverage with complete medical-care coverage in the hospital, then hospital coverage with total medical care coverage.'

The next source I wish to quote from is an eminent, nonprofessional student of medical economics. I refer to Michael Davis, formerly a member of the Executive Committee of the Committee on the Costs of Medical Care and at present chairman of the Committee on Research in Medical Economics and editor of *Medical Care*, the quarterly publication of that committee. An expression of opinion by him on our specific problem deserves to be highly regarded. I quote him both from conversation and correspondence. The conversation can be presented only as my memory recalls it, and hence with the reservation with which recollected statement must be offered. In discussing the question of a partial coverage or a complete-coverage contract as the initial step in a program such as ours, he said that the only certain way of achieving a financially secure base with a complete-coverage contract would be by procuring the co-operation of an industrial establishment which would guarantee from the beginning the necessary 10,000 or more subscribers to a complete medical-care contract, which enrollment is estimated as the minimum figure which will stabilize such a contract financially. In correspondence with him, his full statement—the last sentence of which accepts the principle of an initial step by partial coverage—was as follows:

I believe that the medical profession ought to offer a scientifically designed medical service, utilizing the preventive and therapeutic powers of medicine. A plan under medical society auspices ought, therefore, to include general medical care and specialist service in minor disease and in the early stages of serious disease, as well as service for expensive catastrophic illnesses requiring hospitalization. You may, however, proceed with the aim of getting a prepayment plan promptly under way with enough membership to be self-supporting, rather than from the point of view of basic professional principles. Under such limitations, a service confined to the last named group of illnesses will usually be more salable to industrial workers, chiefly because, in their view, the rate will be lower and the sense of immediate protection stronger.

Where could one find a more lucid, precise statement of our objectives?

Finally, I quote several excerpts from letters received from Mr. R. F. Cahalane, executive director of Massachusetts Hospital Service (Blue Cross), who is in a strategic position to measure the interests and demands of individuals and organizations in Massachusetts. One letter remarked, "My only hope is that your committee can meet soon and as often as necessary to crystallize this whole

thing and get a surgical plan out to the public without delay." In another letter he stated "In our contacts with present subscribing groups and prospective groups we are running into some difficulties because of our lack of surgical coverage. Most of these groups openly admit the one reason for considering commercial groups is the surgical coverage, and everyone admits the superiority of the Blue Cross plans." Another statement was as follows:

Enclosed is another indication of the urgency of getting a surgical plan started. I am enclosing a letter from a subscriber, which was written in reply to a letter from us, inquiring why a subscriber cancelled. This subscriber appears very grateful to Blue Cross for all that has been done for him, but has taken a commercial contract because he can get surgical coverage. The number of instances where my men have occasion to report to me serious competition is rapidly increasing. A number of instances have arisen this week. The only competition exists because we are unable to offer a surgical contract. For this reason I am pleading for prompt action toward this end.

Finally I present a letter from Mr. Cahalane which indicates the reception our first partial-coverage contract will probably receive. He writes:

In getting the list of firms which indicated their interest in the surgical plan, which list was given to the Commissioner of Insurance, I find that a number of interesting answers were made to the question whether they were interested:

*Boston Consolidated Gas Company* Absolutely  
When is it coming?

*Converse Rubber Company* Mr. Berlin, president,  
'If Blue Cross supports and recommends it, we certainly will be interested.'

*Filene's* Mr. Bean, executive assistant, 'The sooner the better.'

*First National Bank of Boston* Mr. Brown, "Very much interested."

*Hood Rubber Company* Dr. Daniels, "Very much interested."

*Lever Brothers* Mr. Kelley, "Very urgent."

*New England Telephone and Telegraph Company*  
Mr. Weir, "Absolutely."

Mr. Spaulding contacted the Heald Machine Company, Norton Company and Whitin Machine Company (Worcester County). He received an O. K. from all of them. I do not have a record of just what the comments were in detail.

Mr. Cunningham made the contacts in Boston, and he reported general enthusiasm on the part of everyone. From this it would appear to me that there will be no problem in getting enrollment.

For these cumulative and convincing reasons your committee recommends (1) the quick preparation of a so-called "surgical contract" (meaning coverage for the expense of hospital surgery, obstetrics and diagnostic x-ray service), (2) preparation, as quickly thereafter as is feasible, of a total hospital medical-care contract to cover all medical fields incidental to hospital medical-care expense, and (3) careful, slow preparation of a comprehensive medical-care contract covering medical care expense in the home, office and hospital, to be presented later.

JAMES C. McCANN, Chairman

## APPENDIX NO. 13

## REPORT OF THE COMMITTEE ON POSTGRADUATE INSTRUCTION

The Society's postgraduate program began this fall with the New England Postgraduate Assembly, which was held October 29 and 30, 1941, in Sanders Theatre at Harvard University. The program was of wide medical interest. The following distinguished physicians made the assembly a notable success:

Dr. Frank E. Adair, New York City  
 Dr. J. Burns Amberson, Jr., New York City  
 Mr. J. J. Bloomfield, Bethesda, Maryland  
 Dr. William Darrach, New York City  
 Dr. John F. Fulton, New Haven, Connecticut  
 Dr. John S. Lockwood, Philadelphia  
 Dr. H. M. Marvin, New Haven, Connecticut  
 Dr. Wm. S. McCann, Rochester, New York  
 Dr. Damon B. Pfeiffer, Philadelphia  
 Dr. Homer F. Swift, New York City  
 Dr. George W. Thorn, Baltimore  
 Dr. Norris W. Vaux, Philadelphia

The assembly attendance by states was as follows:

Massachusetts	..	542
Maine	...	56
New Hampshire	..	31
Vermont	..	19
Rhode Island	..	37
Connecticut	..	14
New York	..	10
Others	..	11
Total	....	720

The finances were satisfactory as the receipts were \$301.41 more than the expenses; this result helps to balance the deficit of last year.

This year the postgraduate extension program has been organized in two divisions—a general course sponsored by the Society, for which there is a registration fee of five dollars, and a course in venereal disease financed by the United States Public Health Service and the State Department of Public Health, for which there is no registration fee. Both these courses are open to all legally registered physicians.

The postgraduate extension program started in Norwood on January 15. The general course will be given in the following places:

Berkshire	Pittsfield
Bristol South	Fall River
Hampden	Springfield
Hampshire	Northampton
Middlesex East	Winchester
Norfolk	Norwood
Norfolk South	Quincy
Worcester	Milford
Worcester North	Fitchburg

The course in venereal disease will be given in the following places:

Berkshire	Pittsfield
Bristol South	New Bedford
Norfolk South (two lectures)	Quincy

No extension program will be offered in the metropolitan area due to the large number of medical-defense courses.

Programs of the above courses were published in the *New England Journal of Medicine*, issue of January 15, 1942; folders giving full data concerning the courses

have been mailed to all registered physicians in the various districts. The committee wishes to express its appreciation for the continued co-operation and helpfulness of the State Department of Public Health.

At the present time the committee is studying the prospect for the New England Postgraduate Assembly for next fall; no final decision has been reached; a further report on this project will be made at the annual meeting.

The committee wishes to express the thanks of the Society to the instructors of the postgraduate extension courses and all those whose efforts helped to make the assembly a success.

REGINALD FITZ, *Chairman*  
 LEROY E. PARKINS, *Secretary*

## APPENDIX NO. 14

Franklin P. Lowry, M.D.  
 313 Washington Street  
 Newton, Mass.

February 3, 1942

Dr. Michael A. Tighe, Secretary  
 The Massachusetts Medical Society  
 8 Fenway  
 Boston, Massachusetts

Dear Dr. Tighe:

I shall be unable to attend the Councilors' meeting tomorrow.

The Committee on Physical Therapy has no definite report to make.

We do, however, have an occasional opportunity to enlighten organizations and individuals about the relative value of the several schools of physical therapy hereabouts.

Should Dr. Ober think best—if time permits—to announce the opening of the second Technicians' Six Months' Course in March, it might be possible that some of those present might know of prospects.

Cordially yours,  
 FRANKLIN P. LOWRY

## APPENDIX NO. 15

## REPORT OF THE COMMITTEE ON MEDICAL PREPAREDNESS

This committee has heretofore had no report to present to the Council. About January 1, however, it became obvious that the committee might soon be expected to play a part in helping out in the Procurement and Assignment Service for physicians in Massachusetts. Accordingly, the following letter was sent on January 9 to the President of each district medical society:

Dear Sir:

It is to be anticipated that the Medical Preparedness Committee of the Massachusetts Medical Society will soon be requested to assist the National Procurement and Assignment Service. It is planned to mobilize the entire medical profession in order to utilize this profession as effectively as possible during the duration of the national emergency. To help in the accomplishment of this, a survey in Massachusetts must be made in order to make it clear what are the medical needs of our community, civilian and industrial agencies, hospitals and so forth. There are enough physicians available to be of service to the Army without in any way neglecting our civilian population.

Committees should now be appointed by the president of each district society. The size of each district committee will vary with the size of the district society. If already a committee for preparedness exists in your district, it should be given the duty of the committee of which I write.

The purpose of such committees will be to study the number and capabilities of all physicians in their districts with a view toward helping to classify them into various groups, such as (1) suitable for military or naval service, (2) to be kept from military service because of being essential to the community, industry or defense work of any sort, (3) unfitted for military service but able to carry on civilian or hospital practice, and (4) unsuitable for any type of medical work because of age or physical infirmity.

My understanding is that such committees are to do nothing at present beyond organizing themselves in readiness to go to work when ordered to do so. This preliminary letter asks you to appoint such a committee as I have outlined in your district, sending to me the names of the men appointed. The size of the committee is left entirely to your judgment. Please ask each member of the committee to read the article which appeared in the December 6 number of the *JAMA*, pages 1983-1987. Make it very clear to each member of your committee that at present the committee is to do no more than make plans for operating when ordered to do so.

Yours sincerely,  
REGINALD FITZ, *Chairman*

The response to this letter was reasonably prompt. Already there have been appointed appropriate committees in the following district societies:

Berkshire	Hampshire
Bristol North	Middlesex East
Bristol South	Middlesex South
Essex South	Suffolk
Hampden	Worcester
Norfolk South	Plymouth

On January 24, the chairman of your committee received a letter from Mr. Paul McNutt concerning the Procurement and Assignment Service for physicians. Parts of this are quoted:

It is planned to have an advisory committee in each corps-area to assist this office in the carrying out of its functions. To supplement each corps-area committee it is planned to have a state committee. I should appreciate it if you would serve as the chairman of your state committee.

As chairman you will be expected to organize your state committee and to set up the necessary committees below the state level which will assist you in obtaining information relative to the availability of physicians in your state who may be asked to volunteer their services elsewhere in the interest of the national emergency.

The function of the state committee will be to coordinate surveys in each state and to assist in the determination of the assets with reference to all physicians residing therein. It is also expected that your committees will provide the information necessary to avoid the indiscriminate dislocation of practitioners who are in essential capacities.

Your chairman agreed to serve in the capacity suggested by Mr. McNutt and now found himself with the necessary committees below the state level in the districts already mentioned, and with plans for the formation

of such committees in all districts. It was left to organize the appropriate state committee.

Your chairman consulted with your president and, as a result, will propose to Mr. McNutt the following names for members of the state committee:

H. M. Clute, Suffolk  
J. J. Curley, Worcester North  
E. L. Kichham, Norfolk  
Dwight O'Hara, Middlesex South  
W. H. Pulsifer, Plymouth

On January 30, the first assignment of work commenced. A list of names was forwarded to your chairman from Washington, comprising a group of forty-five physicians under the age of thirty-six, who already have enrolled with Procurement and Assignment Service with a view to immediate commission in the Army or Navy. This list is to be scrutinized by the appropriate committees in the districts where the men live, to discover if for any reason any of these young doctors should be regarded as unavailable for immediate service.

The following table has been made to give a bird's-eye view of this initial list:

DISTRICT	NUMBER OF CANDIDATES	DISTRICT	NUMBER OF CANDIDATES
Barnstable	0	Middlesex East	0
Berkshire	1	Middlesex North	1
Bristol North	1	Middlesex South	6
Bristol South	1	Norfolk	6
Essex	3	Norfolk South	2
Essex North	1	Plymouth	0
Franklin	1	Suffolk	12
Hampden	4	Worcester	7
Hampshire	3	Worcester North	1

The candidates are widely scattered, suggesting the need for alert committees in each area and that there will be considerable work on the classification of physicians throughout the entire State.

It is gratifying to be able to report that returns from four districts already have been received because the Procurement and Assignment Service in Washington emphasizes the fact that reports on these candidates are required as quickly as possible. The spirit of these returns is praiseworthy in suggesting that the work of classifying doctors in Massachusetts will be done quickly and unselfishly. For example, one chairman reporting for his committee concerning a candidate wrote: "He is one of the most outstanding young surgeons in our community. I dislike very much to say he is available for military service, but in all fairness I cannot say anything else as our community most certainly can get along without him and he should be a great asset either to the Army or the Navy." This is a model of the way in which each doctor should be considered.

It is the work of your committee continues to develop as successfully in future as it has during the first few days of its active existence, its accomplishments should be a credit to the efforts of the Society toward being helpful to the country during the present emergency.

REGINALD FITZ, *Chairman*

## APPENDIX NO 16

### REPORT OF THE COMMITTEE ON REHABILITATION

This committee was formed by the president of the Massachusetts Medical Society at the last regular meeting of the Council, on October 1, 1941. It was formed largely, as we understand it for the purpose of assisting the Division on Health of the Massachusetts Committee on Public Safety, the chairman of which committee is Professor Curtis Hilliard. Several meetings have been attended by

one or more members of your committee in conjunction with Professor Hilliard.

On or about November 14, 1941, the secretary of the Massachusetts Medical Society attended a meeting in Chicago, at which various plans were discussed for rehabilitation of those who, because of various defects, had failed to pass selective-service medical examinations. We are informed that no definite program was adopted at that meeting.

On December 22, 1941, one of us met with Professor Hilliard and others of his committee. We learned on that date that the committee of the Massachusetts Dental Society unofficially endorsed the health program of the Massachusetts Committee on Public Safety. Official endorsement was expected at a meeting to be held later by the Executive Committee of the Dental Society.

The directors and the members of the State Health Executive Committee would appreciate very much a communication from the Council of the Massachusetts Medical Society, endorsing their general program and assuring them of our co-operation and support. Professor Hilliard's committee has done a great deal of work on this matter, and several hundred rehabilitation agents have been named throughout the State. In order to be sure in what way the members of the Massachusetts Medical Society might co-operate with Professor Hilliard and his committee, and in order to be reasonably clear as to the program on which he would be pleased to have our endorsement, we asked him to outline in writing his proposed work, and this he has done in a communication dated January 3, 1942, a copy of which follows:

We are enclosing a copy of the dental statement of the attitude and policy which the Committee on Rehabilitation of the Massachusetts Dental Society are submitting to their Council. While this statement is cautious, I feel that on the whole it can be considered that the dental profession will be sympathetic with our rehabilitation program and it will go along with us as our plans develop.

We would like your committee of the Massachusetts Medical Society to consider recommending to the State Council some expression of their endorsement of the rehabilitation program in general and of the willingness of the State Society to recommend to their membership the co-operation of the local societies and of individual physicians. We do not consider that the plan necessarily involves giving of free medical service or advice. Our rehabilitation agents who are, ordinarily, trained people, may have cases where some leniency in respect to fees and time of payment may be desirable. We would also like from your committee a statement regarding the relation of certain other professional groups to the rehabilitation work. For example, the Boston Society of Optometrists have offered, without stint, the services of their Boston Clinic in the work of rehabilitation and they are placing this matter before their State society. We believe that the ophthalmologists may likewise be drawn into our plan. More difficult is the handling of the chiropodist group who have already offered to help us. (I suppose that then we have just got to be practical but I would like the expression and opinion of your committee.)

These are the chief things that occur to me at the moment on which we would like to act but it may well be that your group will give us some useful advice or suggest some action that they can take which will be helpful to us. We appreciate greatly the time and thought you personally are giving this matter and also the willingness of your colleagues to co-operate.

Pursuant to receipt of this communication, Professor Hilliard was advised that unless time was of the essence, no action would be taken by the Massachusetts Medical Society until the Council meeting which would be held on February 4.

Those in authority who have had to do with the examination of selectees have compiled various groups of statistics. It has been necessary, we are told, to examine five selectees in order to obtain two fit for military service. A great many of those turned down are anxious to have remedial defects attended to. Professor Hilliard's committee is taking a long-range view as to what may be done generally to improve the health of the citizens of this commonwealth. Again, as we understand it, his committee has not for its prime object the rehabilitation of those who wish to be made fit so that they may enter service forthwith. However, at the regular monthly meeting of the Boston Hospital Council held in November, endorsement of Professor Hilliard's work was given with reference to those seeking medical aid in order that they may be admitted to the air forces of our country.

If the Council of the Massachusetts Medical Society to-day approves, the Committee on Rehabilitation will report in substance to Professor Hilliard as follows:

The members of the Massachusetts Medical Society are deeply appreciative of the work undertaken by the State Health Executive Committee of the Massachusetts Committee on Public Safety. Ever since the Massachusetts Medical Society held its first meeting in 1781, its members have felt privileged to be of assistance to those afflicted by disease or injury, or those handicapped because of various defects. We are well aware that many others, not members of the Massachusetts Medical Society, have, so far as their ability permitted, been interested in no small way in measures which have had to do with the health and well-being of our citizens. We are not well enough acquainted with the work and programs undertaken by professional groups who are not physicians but who are interested in the health of our citizens so that we might give blanket approval of their respective programs. The members of the Massachusetts Medical Society are keenly aware of the tremendous amounts of money now being expended in the defense of our country. We believe no programs now in force have effected any change in the status which has long continued to exist and which exists at the present time between physicians and patients in this commonwealth. We do expect reasonable financial remuneration from those who are able to pay for our services as they may be required in this program of rehabilitation. However, not in the past and certainly not now will any members of the Massachusetts Medical Society permit any individual who needs medical or surgical care or advice relative to matters of health to go without these services because the individual is unable to pay for same. From time to time as the Executive Health Committee on Public Safety wishes assistance from the members of the Massachusetts Medical Society, we would appreciate hearing from the Executive Health Committee or from any of the numerous rehabilitation agents throughout the State, and with them we shall endeavor to co-operate so far as we may reasonably and properly do so in this matter of rehabilitation.

# MEDICAL PROGRESS

## ENDOSCOPY\*

EDWARD B. BENEDICT, M.D.†

BOSTON

**A**LTHOUGH endoscopic procedures are naturally best carried out by specialists, the general practitioner is frequently called on to decide whether or not such examinations are indicated. It is for this reason that physicians in general practice must be interested in endoscopic progress, for it is only through the co-operation of all physicians that such examinations are performed on the right patients at the right time.

### ANESTHESIA

Anesthesia for peroral endoscopy has been reviewed by Jackson and McReynolds,<sup>1</sup> who believe that cocaine is the most efficacious drug for local anesthesia, and that if it is used with care, serious reactions will be rare. They believe that Pontocaine is fairly satisfactory but is contraindicated in asthma patients. Larocaine in their experience has been absolutely nontoxic but has also been less effective. General anesthesia is used in the Jackson Clinic very rarely. In my opinion, almost all endoscopic procedures can and should be done under local anesthesia. For some time, all peroral endoscopies in the clinic at the Massachusetts General Hospital have been done under 5 per cent Larocaine, which appears to be sufficiently efficacious and is less toxic than cocaine or Pontocaine. All peritoneoscopies are done with 1 per cent novocain.

### BRONCHOSCOPY

#### *Bronchial Anatomy*

Adams and Davenport,<sup>2</sup> in a very careful study on the technic of bronchography and a system of bronchial nomenclature, have attempted to standardize the various divisions and segments of the five major lobes of the lung. They propose a simplified terminology based on careful anatomic studies that will meet the practical needs of internists, radiologists, bronchologists and surgeons. The use of a common language in describing the tracheobronchial tree will do much toward a correct interpretation of clinical, roentgenologic and bronchologic findings.

\*Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress Annual, 1940* (Springfield, Illinois: Charles C. Thomas Company, 1941, \$4.00).

†From the Massachusetts General Hospital.

Assistant in surgery, Harvard Medical School, associate visiting surgeon, Massachusetts General Hospital.

#### *Use in Various Diseases*

**Bronchiectasis.** Schenck,<sup>3</sup> in a discussion on the etiology of bronchiectasis, observes that the high incidence of sinus disease is not accidental and that therapy of chronic suppurative disease of the lower respiratory tract is doomed to failure if it does not include the thorough treatment of sinus infection. I agree that careful treatment of sinus disease is essential in the care of bronchiectatic patients.

In a recent symposium, it was emphasized that bronchiectasis is frequently a sequela or complication of the pulmonary phase of an acute infectious disease of childhood. In discussing the prevention of bronchiectasis, Tucker<sup>4</sup> states that the expulsive effort of the cough mechanism is much feeble in infants and young children than in adolescents and adults. The retention of the obstructive secretions is favored by this feebleness of effort, and when the effort is obtunded or suppressed entirely by the toxicity of the general infection or by the administration of sedatives, a condition results that is ideal for, and in many cases is undoubtedly the cause of, atelectasis and bronchiectasis in young children. On this basis, Tucker advocates bronchoscopic treatment of children with these conditions and considers the results of aspiration and drainage in such patients remarkable.

Tucker<sup>5</sup> has recently pointed out the value of chemotherapy in the treatment of bronchiectasis. By means of an endobronchial insufflator, he has introduced sulfadiazine into the major bronchi at the time of bronchoscopic aspiration. This form of therapy is well tolerated, produces no bronchial obstruction, and in some cases has resulted in striking improvement. A constant blood level can be maintained. Sulfanilamide may be used, but sulfadiazine is probably better. According to Churchill,<sup>6</sup> peroral chemotherapy may be beneficial in bronchiectasis, but I believe that intrabronchial administration, with aspiration of bronchial secretions at regular intervals, will be of greater benefit. Holinger, Basch and Poncher<sup>7</sup> have made a valuable study on the influence of expectorants and gases on sputum and the mucous membranes of the tracheobronchial tree. They emphasize the fact that drainage of pathologic secretions in the

bronchi depends to a large degree on liquefaction of these secretions by the action of the glands of the more normal bronchial mucosa; by an increase in liquefaction, expectoration is aided. Following the administration of carbon dioxide, patients with low-grade bronchiectasis were found to have less secretion in their bronchi. The secretion was also of a constantly lower viscosity than that noted when carbon dioxide was not used. Carbon dioxide is therefore considered an extremely efficient expectorant. Oxygen, moreover, was found to be definitely antiexpectorant. In bronchiectasis and in certain types of asthma in which bronchial obstruction plays a role, frequent inhalations of carbon dioxide by mask, together with steam inhalations, may be used to augment postural drainage and bronchoscopic aspirations, which are fundamentally important. The use of steam and carbon dioxide between bronchoscopies is indicated if the sputum is known to be extremely thick and tenacious. In laryngotracheobronchitis, the use of a room kept at 70 to 75°F., together with a relative humidity of 80 to 95 per cent, provides satisfactory conditions for liquefying secretions. If oxygen administration is necessary, a high degree of humidity in the oxygen tent is essential. A combination of steam inhalation and carbon dioxide has been found to be the most efficient expectorant in the treatment of postoperative massive collapse. When these methods fail, bronchoscopic suction must be used. Carpenter, Kerr and McMurray,<sup>8</sup> who have treated a group of 38 cases of bronchiectasis by x-ray therapy, conclude that such therapy is only moderately satisfactory. They do believe, however, that it may be a valuable adjunct in the treatment of patients whose pulmonary lesions are not amenable to surgery and whose symptoms have not been relieved by other forms of treatment, such as bronchoscopic and postural drainage.

Bradshaw, Putney and Clerf<sup>9</sup> made a follow-up study of 242 cases of untreated bronchiectasis. They report that the average duration of life from the onset of symptoms to the time of death was over thirteen years. They believe that young children with definite evidence of bronchiectasis may later show no evidence of the disease—lack of symptoms and negative studies with iodized oil; in other words, bronchiectasis in early childhood may sometimes be cured by proper bronchial drainage.

*Postoperative pulmonary complications.* The use of the bronchoscope in the postoperative aspiration of secretions is becoming more widely recognized by general surgeons. Allen<sup>10</sup> believes that bronchoscopy for this purpose is so vital that all

anesthetists should be trained in its technic. Such training is now being carried out at the Massachusetts General Hospital.

*Lung abscess.* Moersch and Olsen<sup>11</sup> report on the value of bronchoscopy in the diagnosis and treatment of pulmonary abscess: the procedure established the exact location of the abscess in 22 out of 264 cases. They report very good results from the bronchoscopic treatment of lung abscess. I consider this a debatable subject, however, since some cases of lung abscess are cured under medical treatment and others under a combination of medical and bronchoscopic treatment, whereas many require surgical drainage and a few are best treated by lobectomy. Lung abscess, therefore, like many other pulmonary conditions, is best handled by the internist, thoracic surgeon, bronchoscopist and roentgenologist, all working together.

*Carcinoma.* Betts<sup>12</sup> divides pulmonary carcinoma into central and peripheral groups, depending on the site of origin of the lesion. He regards the central group as more favorable from a therapeutic standpoint because such lesions produce symptoms earlier than the ones distally situated; because they can be visualized and biopsied bronchoscopically, which permits an early positive diagnosis; and because there is evidence<sup>13</sup> that tumors in the central location grow more slowly and metastasize later than lesions situated peripherally. In peripherally located tumors, aspiration biopsy is sometimes of use, although, as Franseen<sup>14</sup> points out, there is some risk of implantation in the chest wall and pleural cavity.

*Benign tumors.* Goldman and Stephens<sup>15</sup> call attention to the fact that pulmonary resection appears to be the ultimate fate awaiting most patients with bronchial adenoma. This is so not only because of the persistence of the tumor itself but also because of the presence of distal pulmonary suppuration. I agree with this and, in fact, have recently pointed out that only a few cases of bronchial adenoma are completely cured anatomically as well as clinically by the bronchoscopic method.<sup>16</sup> The failure to obtain complete cure by bronchoscopy alone is due to the occurrence of irreparable lung damage distal to the tumor, to the recurrence locally of the adenoma and to the extrabronchial growth of the lesion. Bronchoscopy, however, is of great value in the diagnosis of adenoma, and in some cases, bronchoscopic removal results in almost complete relief of symptoms.

*Tuberculosis.* Davenport<sup>17</sup> has studied 10 cases of tuberculous tracheobronchitis with special reference to x-ray therapy, which he believes to be of benefit in the acute obstructive stage of the dis-

er. In occasional cases, Benedict<sup>18</sup> has noted unquestionable benefit from dilatation of a tuberculous stricture, with the consequent release of retained secretions.

## ESOPHAGOSCOPY

### *Use in Various Diseases*

*Carcinoma* Garlock<sup>19</sup> believes that cancer of the esophagus is usually a slow-growing neoplasm and that the next few years will see the acceptance of surgical treatment as the only sound therapy. More rapid progress in the surgical treatment will be made when increasing numbers of early cases (patients with persistent dysphagia) in which esophagoscopy, biopsy, fluoroscopic and roentgenographic examinations have been done are referred to the surgeon. In a recent discussion on the surgical treatment of carcinoma of the esophagus, Adams<sup>20</sup> remarks that the frequency of this disease has only recently become appreciated. He finds that it ranks fourth in incidence of all malignant tumors in men over twenty years of age. Successful operative management depends almost entirely on early diagnosis, and early diagnosis, in turn, depends on the education of the profession as a whole to the awareness of the gravity of dysphagia and the value of immediate x-ray and esophagoscopic examinations. In a discussion on carcinoma of the esophagus from the point of view of the endoscopist, Benedict<sup>21</sup> has emphasized the fact that by early diagnosis an increasingly large proportion of the patients with carcinoma of the esophagus may be cured by radical surgery. Churchill<sup>22</sup> and Sweet<sup>23</sup> have demonstrated the great value of the transthoracic approach in surgery of the lower esophagus and upper stomach. When, however, patients are seen too late in the disease for surgery, much can be accomplished in the way of palliation by x-ray treatment combined, if necessary, with bouginage. Gastrostomy is seldom necessary.

*Benign stricture* Hara and Rosenfold,<sup>24</sup> in a discussion of cicatricial atresia of the esophagus, call attention to the advantage of using a cystoscope for retrograde esophagoscopy, since it reveals a wider area and gives a better view of the field than can be obtained through an open tube esophagoscope. The cystoscope is introduced through a gastrostomy wound and insinuated into the esophagus under visual guidance. A ureteral catheter may then be introduced upward through the stricture, with fluoroscopic guidance, if necessary.

*Cardiospasm* Ochsner and DeBakey<sup>25</sup> have recently discussed the surgical treatment of achalasia

of the esophagus, believing the soundest surgical procedure to be esophagogastrostomy, the technic of which is illustrated. They find that slightly less than one third of the cases require surgical intervention. It is my opinion, however, that more than 90 per cent of these cases can be satisfactorily treated by conservative measures.

*Varices* Moersch<sup>26</sup> has made a further report on the treatment of esophageal varices by injection of sclerosing solutions. He is now using 5 per cent sodium morrhuate and giving injections of 5 to 7 cc twice a week. In a series of 11 patients, four hemorrhages occurred subsequent to treatment. Further experience will be necessary before the method can be finally evaluated, but there is some evidence that the hemorrhages are less frequent and less severe.

*Syphilis* Kampmeier and Jones<sup>27</sup> have reported 4 cases of esophageal obstruction due to syphilis, 1 was the result of a gumma of the esophageal wall, and 3 were caused by gummatous lesions of the diaphragm at the esophageal hiatus. The symptoms are those of esophageal obstruction. The diagnosis is made by serologic and roentgenologic examinations, in addition to esophagoscopy and biopsy. Three of the 4 patients were cured by antisyphilitic treatment and dilatation of the esophageal strictures. One case was diagnosed as carcinoma of the esophagus, and the patient died without receiving appropriate treatment.

### *Relation of Nutritional Deficiency to Dysphagia*

Merrill and Richards<sup>28</sup> have re-emphasized the significance of nutritional deficiency and its relation to dysphagia, concluding that difficulty in swallowing is occasionally a result of neuritis involving the ninth or tenth cranial nerve, which in turn is produced by nutritional deficiency, particularly of the vitamin B complex.

### *Influence of Psychic Factors on Esophageal Tone*

Faulkner,<sup>29</sup> in an esophagoscopic study of 13 cases, has observed esophageal changes due to psychic factors. During inspection of the esophagus, he has shown that disturbing thoughts and emotions produce esophageal spasm. This spasm can be increased and the esophageal lumen narrowed or closed by suggestions that call forth destructive emotions, such as grief, anger, anxiety, apprehension, fear and spiritual imprisonment. The esophageal spasm relaxes when proposals are made eliciting such emotions as happiness, elation, enthusiasm, contentment and security. I believe that this is a difficult matter to prove, since respiratory, circulatory, traumatic and other factors come into the picture.

## GASTROSCOPY

*Indications*

Since it is imperative for physicians to know when special procedures should be used, Benedict<sup>30</sup> has listed the indications for gastroscopy as follows: gastritis; unexplained gastrointestinal hemorrhage; so-called "gastric neurosis"; unexplained persistent gastrointestinal symptoms, with negative or inconclusive x-ray examination; gastric ulcer, to determine the appearance and location of the lesion, to differentiate benign from malignant ulcer, and to follow the healing process in benign ulcer; duodenal ulcer, to study the gastric mucosa for the presence of gastritis, gastric erosions or gastric ulcerations; carcinoma, to determine the gross appearance, extent and operability of the lesion; polyposis; the so-called "postoperative stomach"; and occasional cases of suspected foreign body in the stomach.

*Gastroscopy in the Armed Forces*

Schindler,<sup>31</sup> who has recently discussed the advantage of the gastroscope in the diagnosis of gastric diseases in soldiers, concludes that the differential diagnosis of psychoneurosis and chronic gastritis in patients suffering from epigastric distress is of great consequence to all branches of the armed forces. The cases presented prove that this differential diagnosis is possible only by the use of the gastroscope. Most patients who refuse examination and fail to co-operate are malingerers. Facility for gastroscopy should be available to all military hospitals.

*Gastroscopic Method*

To determine the safety of gastroscopy, Schindler<sup>32, 33</sup> sent out a questionnaire and received replies from sixty gastroscopists, who reported their experiences during 22,351 gastroscopies. In this series, there was one death that must probably be attributed to the use of the gastroscope. Thus, the fatality of gastroscopy is 0.004 per cent, or practically nil.

Kenamore<sup>34</sup> has reported the invention of a biopsy forceps to be attached to the flexible gastroscope. He claims that the instrument can be employed effectively in any portion of the stomach that is visible gastroscopically. I believe that this may be an important advance in gastroscopic technique in carefully selected cases.

*Use in Various Diseases*

*Alcoholic gastritis.* Gray and Schindler<sup>35</sup> have recently reported the gastroscopic appearance of the gastric mucosa of chronic alcoholic addicts. Examination of 100 men who had consumed an average of 2.8 pints of distilled liquors daily for

more than twenty years revealed that the stomachs of 55 per cent were essentially normal. The gastric disease observed in 45 per cent consisted mainly of superficial gastritis, atrophic gastritis or a combination of the two. Mucosal hemorrhages occurred in 22 per cent. Severe or moderately severe gastritis was accompanied by definite symptoms in 60 per cent, whereas only 7 per cent of the addicts with normal stomachs had gastrointestinal complaints. No correlation was observed between the incidence and severity of the gastritis and the duration of the alcoholism, the amount of alcohol drunk, the abuse of nicotine, dental infection or vitamin deficiency. The cause of the gastritis observed in 45 per cent of the cases was not clear, but might be ascribed to an individual sensitivity to alcohol or to a deficiency disease, although apparently not specifically to a vitamin deficiency. These observations are borne out by Berry,<sup>36</sup> who also studied 100 patients with unquestionable chronic alcoholism of long duration and found that 30 per cent did not have gastritis, 35 per cent had mild chronic superficial gastritis and only 35 per cent had unequivocal chronic gastritis.

*Chronic gastritis.* McClure, Sweetsir and Janekelson,<sup>37</sup> in a gastroscopic and clinical study of chronic gastritis, have emphasized the significance of hematemesis as a complication of this disease. They also believe that fatigue is a major symptom characterizing primary atrophic gastritis. The presence of chronic gastritis can apparently be demonstrated only by means of gastroscopy.

Kelley, Lawlah and Berry<sup>38</sup> studied the gastric mucosa by the x-ray relief technic and correlated their findings with the gastroscopic diagnosis in 150 cases of benign and malignant gastric neoplasm, ulcer and chronic gastritis. They conclude that the relief method demonstrates these lesions accurately except in chronic gastritis, and that if one attempts a diagnosis of chronic gastritis by x-ray it should be done with great reservation.

*Atrophic gastritis.* In discussing the treatment of atrophic gastritis, Schiff and Goodman<sup>39</sup> present the case histories of 5 patients treated by desiccated hog's stomach extract (Ventriculin), with marked symptomatic improvement and disappearance of the atrophic changes. These results suggest that atrophic gastritis, perhaps better called "gastric atrophy," in some cases may be a deficiency disease. This is further corroboration of the evidence originally presented by Jones, Benedict and Hampton,<sup>40</sup> who showed that in pernicious anemia the changes characterizing gastric atrophy may disappear following liver therapy.

**Post-operative gastritis.** Moersch and Walters<sup>41</sup> have made gastroscopic observations in cases of gastric distress following operations on the stomach and conclude that, contrary to the commonly accepted teaching that gastritis is found in all stomachs after operation, 30 per cent of this series of cases failed to show gastroscopic evidence of disease. Evidence of gastritis was present, however, in 56 per cent of the cases studied. In speculating on the possible factors in postoperative gastritis, the writers believe that in many cases a pre-existing gastritis is responsible. In their opinion, a poorly placed stoma with inadequate drainage of the stomach is a major factor, in addition, if the stoma retains an activity resembling that of a sphincter, gastritis is not so likely to develop. Infection undoubtedly constitutes an important exciting factor.

**Ulcer.** Walters and Clagett<sup>42</sup> discuss the value of gastroscopy in the diagnosis of gastric ulcer, pointing out that although the accuracy of roentgenologic diagnosis of lesions of the stomach is remarkably high, there is always the chance that a small lesion or one situated high in the stomach may be overlooked. Gastroscopy should always be considered in a patient in whom there is a suggestion of a gastric lesion, even though the roentgenologic examination does not reveal any abnormality. Gastroscopy is of considerable value in distinguishing between a benign gastric ulcer and a malignant ulcer and may offer valuable information concerning the operability of the lesion. Gastroscopy is also a great aid in determining the effect of medical management on gastric ulcers. The authors do not consider gastroscopy necessarily a routine procedure in all gastric examinations but have found it to be a valuable adjunct to clinical and roentgenologic study of selected cases of known or suspected gastric disease.

Eusterman,<sup>43</sup> in a paper on carcinomatous gastric ulcer states that the most reliable evidence regarding the extent of healing of a gastric lesion is undoubtedly afforded by gastroscopic examination. When physicians and surgeons who do not do gastroscopy themselves make such statements, one may conclude that the value of the gastroscopic method is now becoming widely recognized.

**Carcinoma.** In several exhaustive studies of carcinoma of the stomach, Schindler<sup>44</sup> has emphasized the status of chronic gastric atrophy as a precancerous condition. He believes that this is a frequent disease, and that an accurate diagnosis is made only by gastroscopy. Clinically, these patients may have long periods of freedom from symptoms, but they usually complain of minor

epigastric distress, pressure, belching or pain. The general symptoms of extreme fatigue, nervousness, numbness and tingling of the limbs are most characteristic. Schindler observes that patients with gastric atrophy or atrophic gastritis are three times likelier to develop gastric carcinoma than other healthy adults. The advantage of frequent x-ray and gastroscopic examinations in such patients is therefore obvious. With regard to the classification of gastric carcinoma, Schindler and his associates<sup>45</sup> have noted that the ultimate prognosis of patients suffering from gastric carcinoma does not depend on the size of the tumor or, apparently, on the microscopic structure of the tumor. They therefore suggest the adoption of Borrmann's classification, based on the gross appearance. In this grouping, Type 1 is the polypoid carcinoma characterized by a broad base supporting a hemispherical elevation, which is solid and whose surface consists of numerous nodes of different sizes; the edge of the growth is sharply limited, and it is often overhanging in a mushroom-like manner. This type is found in 2.9 per cent of all cases. Type 2, the noninfiltrating, carcinomatous ulcer, consists of a lesion that is usually rather large. Its color, as seen in the gastroscope, is a dirty gray or a brilliant white, brownish, purplish and reddish hues being frequently present; this ulcer is surrounded by a thick, high, usually nodular wall, which is limited sharply toward the surrounding gastric mucosa and slopes steeply toward it. This type has been found in 17.6 per cent of all cases. Type 3, the infiltrative carcinomatous ulcer, comprises a lesion that lies in the center of a marked elevation. At one side of it, a wall may be found that is either smooth or, more frequently, nodular; there is a gradual infiltration into the surrounding mucosa, and the wall never surrounds the entire ulcer. Type 3 carcinomas occur in 16.3 per cent of all cases. Type 4 is the diffuse infiltrating type, with no sharp limitations. Shallow or deep ulcerations are frequent, and gastroscopic as well as x-ray examination teaches that such ulcers may heal for some time, other ulcers developing at other places of the carcinomatous infiltration. This type occurs in 63.2 per cent of all cases. Schindler et al conclude that classification of gastric carcinoma, with consideration of its ultimate prognosis, should be attempted and that histologic criteria according to the usual conceptions, especially grading, seem not to have a relation to the gross appearance of gastric carcinoma, to its clinical course or to its surgical curability. Therefore, new attempts should be made to find histologic criteria in better accord-

ance with those factors. Gross classification has proved to be satisfactory. The preliminary impression is gained that excellent results after surgical interference are to be expected with the non-infiltrating lesions (Types 1 and 2), whereas the prognosis with infiltrating lesions (Types 3 and 4) is unfavorable. Needless to say, this requires confirmation by extensive research. In my opinion, the findings are significant, and extensive gastroscopic observations regarding gross typing of tumors should be made. It should be borne in mind, however, that the gross typing is not always a simple matter.

### PERITONEOSCOPY

#### *Method*

In a preliminary report, Robinson and Fiske<sup>46</sup> describe an instrument for retraction of the viscera during peritoneoscopy. In selected cases, this may lead to a widening of the usefulness of the procedure.

#### *Evaluation*

Garrey<sup>47</sup> states that in 25 per cent of the cases he has examined by peritoneoscopy, the findings fundamentally altered the treatment. In the remainder, accurate confirmation of a suspected diagnosis was obtained. He concludes that the procedure is essential to the study of abdominal tumors and liver disease, if needless laparotomies are to be avoided. He emphasizes the fact that it involves only a fraction of the expense or mortality of a major operation. Benedict<sup>48</sup> in an analysis of 300 peritoneoscopies, concludes that it is a safe, simple and accurate method of diagnosis by direct inspection of the abdominal cavity, including the pelvis, and that it will frequently lead to a positive diagnosis not obtainable by any other method except exploratory laparotomy. A positive biopsy was obtained in 100 cases as follows: carcinoma 70, cirrhosis 21, tuberculosis 4, hepatitis 2, sarcoid 1, sarcoma 1 and granuloma 1. Unnecessary exploratory laparotomy was avoided in 37 per cent of the cases.

In a discussion on the value of peritoneoscopy in gastroenterology, Benedict<sup>49</sup> has emphasized the advantage of this procedure in carcinoma of the stomach to avert operation in inoperable cases. It is also indicated occasionally in carcinoma of the colon, rectum, pancreas, liver and gall bladder, especially to differentiate cirrhosis and neoplasm. Also of interest to the gastroenterologist is its use in tuberculous peritonitis and in the

differentiation of ascites due to pelvic disease and that due to cirrhosis.

#### *Use in Various Diseases*

*Primary carcinoma of the liver.* One of the principal uses of peritoneoscopy is in the diagnosis of liver disease, especially carcinoma. Although metastatic carcinoma is far commoner than primary carcinoma of the liver, the latter occurs with sufficient frequency to be of interest. It almost always occurs secondarily to a pre-existing cirrhosis. Although rare in Europeans, Berman<sup>50</sup> reports that it is very common among most pigmented races. In the Bantu races of South Africa, he states that it is by far the most frequent type of carcinoma, since it is responsible for 90.5 per cent of all cancers. Metastasis is frequent. Thirty-one of 54 cases (57 per cent) showed secondary deposits outside the liver. Of all organs, the lungs were the most readily involved; there were 21 cases of lung involvement, in 25 of which both lungs were affected. Next most frequently involved were the regional lymph nodes (8 cases). Other organs affected were the pancreas, diaphragm, omentum, gall bladder, mesentery, peritoneum, pleura, heart, ribs, sternum and brain.

*Carcinoma of the ovary.* In an article on carcinoma of the ovary, Meigs<sup>51</sup> states that there can be no doubt of the value of peritoneoscopy in this group of patients and that it must be used more frequently in diagnosing these tumors. In my opinion, this is a well-established fact. In many cases of unexplained ascites, ovarian tumors with peritoneal metastases have been demonstrated by the use of the peritoneoscope. In a few cases in which radical mastectomy had been performed for carcinoma of the breast, ascites later developed and was thought to be due to metastatic disease from the breast. Peritoneoscopy, however, disclosed a primary malignant lesion in the ovary, with peritoneal metastases. X-ray therapy, with or without oophorectomy, was then carried out.

*Cirrhosis.* Mann<sup>52</sup> has repeatedly emphasized the fact that liver function may be impaired in one respect but not in others. Paulson<sup>53</sup> has also stated that the multiple functions of the liver require the use of multiple tests. Mateer, Baltz, Marion and Hollands<sup>54</sup> stress the advantage of performing several hepatic-function tests in an adequate evaluation of the liver function. The significance of recognizing acute hepatitis has been shown by Krarup and Roholm,<sup>55</sup> who by means of aspiration biopsy demonstrated a gradual transition in 12 cases of grave protracted or recurring hepatitis—from the usual acute hepatitis to fully developed Laennec's cirrhosis. None of

the patients in question were addicted to alcohol. Bearing in mind the inadequacy of liver function tests, I believe that during observations of the liver with the peritoneoscope, peritoneoscopic biopsy is superior to aspiration biopsy and will assume an increasingly important role in hepatic diagnosis.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28111

#### PRESENTATION OF CASE

A sixty-five-year-old housewife was admitted to the hospital because of pain in the chest.

The patient was quite well until about an hour before entry, when, while talking to a friend, she suddenly became unconscious. After about an hour, when consciousness was regained, she complained of pain in the chest, described as a sense of suffocation and pressure between the scapulas, extending to the arms, the anterior and posterior parts of the neck and to the ears. She also complained of headache. There was some gagging, but no vomiting occurred. A physician found the patient to be pulseless, but restless, with active reflexes. There was no stiffness of the neck, the tongue was straight, and pupils were equal, with normal reactions. Morphine was given and the patient was referred to the hospital.

A brother of the patient died of tuberculosis at the age of thirty. During childhood, the patient had pleurisy. At the age of nineteen, she had typhoid fever. During convalescence from this illness, she had great difficulty in swallowing. At thirty-five years, after the birth of her second child, she was again unable to swallow for sixteen days. A year later, a physician found an esophageal stricture, which was then treated by dilatation. After that, the patient had to grind up all her food. When fifty-seven years old, she consulted a physician because of a mass in her neck consistent with an enlarged thyroid gland. The facies suggested myxedema. The heart and lungs were normal. The blood pressure was 115 systolic, 90 diastolic. The basal metabolic rate was -2 per cent. Small doses of thyroid were given, with some decrease in the size of the goiter. Two years later, after a nervous upset, the patient fainted in the street. She felt weak for four or five hours subsequently, but had no other ill effects; the blood pressure was 115 systolic, 85 diastolic. The thyroid gland felt cystic. A slight systolic murmur was heard all over the chest when the patient was supine. A year later, there was another attack of fainting. Two years later, the patient had bronchopneumonia, during which there was a paroxysm of auricular fibrillation.

The blood pressure was 160 systolic, 105 diastolic, but several months later returned to 104 systolic, 72 diastolic.

On admission, the patient was restless, quite talkative and slightly euphoric, although obviously very ill. The skin was ashen. The hands and feet were cold, but dry. The carotid pulse was weak, and no pulsations could be obtained in the extremities. The heart sounds were of good quality and fairly regular, although there were frequent premature beats. A blowing systolic murmur, loudest at the base, was transmitted to the neck and was also very loud over the back. There was no friction rub. The area of cardiac dullness was of normal size. The breath sounds were tubular posteriorly, but there were no rales or areas of dullness in the lung fields. The abdomen was rather rigid, but not tender. The liver and spleen were not palpable. Peristaltic sounds were distant. The veins of the neck were not distended, but the veins over the abdomen formed a distinct caput medusae. The neck was flexible and the reflexes normal.

The temperature was 97°F., the pulse 60, and the respirations 18. The blood pressure was not obtainable at first, but was 70 to 75 systolic, 60 diastolic, in each arm on the second hospital day.

Examination of the blood showed a white-cell count of 12,500. No other laboratory data were obtained.

An electrocardiogram showed normal rhythm with a rate of 75. In the limb leads, the T wave were low, but the ST segments remained upright, without displacement. R<sub>4</sub> was upright. There was a rather sharp, late inversion of T without displacement of the ST interval. There was no abnormal axis deviation, and the P wave and PR intervals were normal.

On the second hospital day, the temperature rose to 101°F., and the pulse rose to 100. The patient complained of headache, but felt well otherwise, the chest pain having abated. About thirty hours after entry, she suddenly gasped, took several deep breaths and expired. Immediately afterward, it was noted that the skin of the face and chest was mottled.

#### DIFFERENTIAL DIAGNOSIS

DR. WILLIAM B. BREED: Before appraising the final episode, which lasted only thirty-one hours, I should like to consider some of this patient's previous experiences in an attempt to see what can be eliminated as being nonsignificant. First of all, there is the story of recurrent fainting. "Fainting" is a term that needs defining. One type is simple fainting, which is a physiologic reaction to environment occurring in certain peo-

ple with emotional instability. Then there is the carotid sinus syndrome, which does cause syncope, but I do not see that we need more than mention it as a possibility. Also, there is the Stokes-Adams syndrome, which causes syncope and with which everyone is familiar. Paroxysmal tachycardia and fibrillation often cause syncope if they are severe enough and last long enough. I am prepared to eliminate the history of recurrent "fainting" as being significant in the patient's last illness, because we have no evidence to support any of the above diagnoses. An enlarged thyroid gland is mentioned that was considered cystic and was said to be reduced in size somewhat after the administration of small doses of thyroid. There is, however, no mention of it on physical examination here in the hospital, and I shall therefore disregard it as being of any importance. The esophageal stricture that was found by the patient's physician and was dilated may be of some consequence. It was of thirty years' duration, and for thirty years she had ground up her food, therefore, in spite of dilatation, the constriction of the esophagus must have persisted. The direct relation of that to the present episode I shall discuss later; it must be kept in mind. We do not, of course, know at what level the stricture was along the course of the esophagus.

What does the terminal episode signify? It was very sudden in onset, and a very simple affair, apparently; the patient simply became unconscious. And then after an hour, she regained consciousness, complaining of a suffocation and pressure in her chest; this sensation extended up the back to the arms and ears. It is perfectly possible that the attack of unconsciousness was not associated with any pain. On the other hand, it is also possible that the patient had a great deal of severe pain and, because of shock, became unconscious without having time to complain of it. If it was really a painless syncope, we must consider the Stokes-Adams syndrome, cerebral hemorrhage, pulmonary embolus and the carotid sinus syndrome. If the terminal episode was associated with a great deal of pain, enough to cause shock and unconsciousness, we must consider severe coronary occlusion, dissecting aneurysm of the aorta, rupture of a syphilitic aneurysm or of the esophagus into the mediastinum, subarachnoid hemorrhage and some of the paroxysmal cardiac arrhythmias.

Before trying to fit a diagnosis to this process, let us first try to make up our minds whether it was due to an intracardiac lesion or an extracardiac lesion. I am going to assume as a working hypothesis that it was an extracardiac process. I say that because the heart sounds were good,

not rapid or irregular. Also, the electrocardiogram, according to my interpretation, indicates merely some mild myocardial insufficiency, and perhaps a very old coronary occlusion. There is nothing in it to suggest recent coronary occlusion. Of course, we know that the electrocardiograph is not 100 per cent correct, but with good heart sounds, and at the same time an obliteration of peripheral arterial pulsation, I think it is fair to assume that this was an extracardiac lesion. By so doing, we automatically rule out the Stokes-Adams syndrome and coronary occlusion.

Cerebral hemorrhage must be considered, but the picture is not one of cerebral hemorrhage. The patient had recovery of consciousness after an hour, with no disturbance in reflexes. Pulmonary embolism is another possibility, but like wise there was the quick recovery after an hour, with no distention of the neck veins. To have produced unconsciousness so quickly, a massive embolism would have been necessary, and there is no evidence that it was massive. The carotid sinus syndrome is possible, but we have no evidence for it.

Could the patient have had a dissecting aneurysm of the aorta? She certainly could. That is a diagnosis that we must consider seriously, particularly with obliteration of pulse, good condition of the heart on direct examination and a negative electrocardiogram. Then the question whether there was some rupture of a viscus into the mediastinum comes up. We have no evidence of syphilitic aortitis with aneurysm.

Is it true that there is no x-ray film?

DR. TRACY B. MALLORY. There is none.

DR. BREED. I was hoping, so long as they had time for an electrocardiogram in thirty hours, that they had x-rayed the chest. A film would have been worth much more to me than an electrocardiogram.

There is no evidence of a rupture into the mediastinum. We have a story of an esophageal stricture, which might have perforated. We do not know where it was located. There may have been a hemorrhage from that stricture, or rupture and hemorrhage combined. Was there a rupture of an aneurysm somewhere in the chest? I should think it quite unlikely, if the aneurysm had ruptured, that the patient would have recovered after an hour and lived reasonably comfortably for thirty hours.

Subarachnoid hemorrhage must be mentioned because of a case that we had recently in which there was subarachnoid hemorrhage about the spinal cord only. The setup before death was so like a dissecting aneurysm that the diagnosis remained that until the post mortem examination.

It was a very unusual picture, and I should hardly think that there would be another case so soon as this. If it was subarachnoid hemorrhage, I cannot make the diagnosis. Therefore, at the moment, the decision in this case lies between a dissecting aneurysm of the aorta and rupture of the esophagus into the mediastinum, with or without hemorrhage.

I should like to comment on a few physical signs in relation to a possible perforation into the mediastinum. The cardiac dullness was of normal size, which again helps to put this in the extracardiac category. The breath sounds were tubular posteriorly, with no rales or areas of dullness in the lung fields. I am loath to accept one observation with no other pulmonary signs, and attach much significance to it. On the other hand, the possibility that something in the mediastinum collapsed the lungs and produced tubular breathing is tempting. It is a pity there was not some dullness or some other sign to go with it. I am not very familiar with perforation of the esophagus into the mediastinum. I do not believe that any of us are. We do not see it very often. We see or hear about dissecting aneurysm of the aorta much more frequently. I suppose, on the pathological chances, I should lean toward that and I think I shall, but I cannot relinquish the distinct possibility that there was a filling of the mediastinum by hemorrhage from a rupture of the esophagus.

I have never seen a caput medusae produced in thirty hours. I must assume that this patient had portal cirrhosis, with obstruction, over a period of years producing a caput medusae, and that it had no relation to the condition with which we are confronted.

I have to make one definite diagnosis. It is dissecting aneurysm of the aorta. A second diagnosis, not a very close second, is rupture of the esophagus into the mediastinum.

DR. MAURICE FREMONT-SMITH: I followed this patient for ten years, and I cannot tell you where the esophageal stricture was. A nose-and-throat man was taking care of her. I examined her a month before her last illness, and she was in good condition, felt well, and had a systolic blood pressure of 142. The story of the acute episode has a little different emphasis from what was given to it in the history.

DR. BREED: I suspected that because it is a peculiar setup.

DR. FREMONT-SMITH: I was called on the telephone by a physician who said that the patient was talking to her minister about the baptism of her grandson, very happily, and without strain, and suddenly became unconscious; *sixty seconds*,

not sixty minutes, later she was again conscious. That is my mistake in the record. She complained of severe pain, not chiefly in the chest or in the back, but in the ears; there was some pain in the chest and in the back of the neck, but not in the back. I asked the doctor whether the patient's neck was stiff, and he said, "Wait a minute, and I shall see." He told me that her neck was not stiff. He gave her morphine and sent her to the hospital. When she arrived, she was a very sick woman and was pulseless.

DR. BREED: In all the extremities?

DR. FREMONT-SMITH: I cannot tell you, since I did not check all the extremities. She was pulseless at the wrist, with a slow heart rate. The sounds were good. A loud systolic murmur, which was new and was heard also between the scapulae had developed. The patient had a fairly high white-cell count—12,000. She did not seem to have any great pain. She had been given morphine. The next morning, the resident at the Baker Memorial told me that he could feel a good pulsation in the dorsalis pedis artery, but at the same time it was impossible to feel any pulse in the wrist. At that time, the blood pressure was 110 systolic, 60 diastolic. That evening, she suddenly died.

DR. BREED: How about the tubular breathing?

DR. FREMONT-SMITH: We just noted that it was there.

DR. BREED: You did not attach any significance to it?

DR. FREMONT-SMITH: Oh yes; we did.

DR. BREED: I am sorry I made that remark about the x-ray versus the electrocardiogram.

DR. FREMONT-SMITH: Not at all. I shall tell you why it was not done. An x-ray film taken in 1940 showed the transverse measurement of the heart within normal limits. The heart showed some prominence in the region of the left ventricle. There was marked tortuosity of the aorta with a distinct bulge to the right in the ascending portion.

DR. BREED: That is comforting so far as the diagnosis I suggested is concerned. May I ask what the clinical diagnosis was at death?

DR. FREMONT-SMITH: I am sorry you asked that. Several of us had suggested dissecting aneurysm, but the final diagnosis was coronary thrombosis.

DR. ALLEN G. BRAILEY: Where did she have tubular breathing?

DR. FREMONT-SMITH: Around the angle of the left scapula.

#### CLINICAL DIAGNOSIS

Coronary thrombosis.

(Dissecting aneurysm of aorta?)

## DR. BREED'S DIAGNOSIS

Dissecting aneurysm of aorta.

(Perforation of the esophagus, with mediastinitis?)

## ANATOMICAL DIAGNOSES

Dissecting aneurysm of ascending aorta, with extension into the great vessels of neck, including complete, transverse rupture of inner aortic cylinder and rupture of outer cylinder into pericardium.

Hemopericardium, massive.

Dilatation of ovarian veins, marked.

Caput medusae.

Adenoma of thyroid gland.

## PATHOLOGICAL DISCUSSION

DR. MALLORY: At post-mortem examination, the first thing that was obvious was a greatly distended pericardium, containing several hundred cubic centimeters of dark, fluid blood in which the heart could be readily ballotted. On opening of the pericardium, it was obvious that the wall of the aorta was hemorrhagic and that there was a rent in it just a little above the level of the aortic valve, about 1 cm. in length, from which this hemorrhage into the pericardium had evidently occurred. On cutting into the aorta, the wall was found to be very thin, barely a third as thick as normal, but then much to our surprise we could not find any sort of inside of the aorta. Just above the valve, the inner segment of the aorta was torn completely across, perfectly smoothly, as if it had been cut across with an amputation knife, and for a moment or two we could not find the rest of it. Finally, it appeared up near the arch, several centimeters from the lower part. Then it became clear that this was a dissecting aneurysm extending from the aortic valve through the arch and 2 cm. down the descending aorta, and that the inner cylinder had spontaneously torn completely across, something we have not seen before. Whether the strange murmur that Dr. Fremont-Smith heard in the scapular area was produced by the free upper end of the inner cylinder flapping in the stream, I do not know. The dissection had also spread a limited distance into the innominate, both carotid and both subclavian arteries, narrowing all these vessels and thus accounting for the diminished pulse in the two arms. The heart itself was not hypertrophied. The coronary arteries were wide and capacious, with a slight amount of atheroma but no narrowing at any point.

We were naturally interested in the caput medusae that had been described. It was evident even post mortem, and to go along with it we found that the ovarian veins were markedly dis-

tended. That is usually a sign of obstruction in the caval rather than in the portal circulation, but the most careful dissection of both portal vein and the inferior cava showed absolutely no obstruction. The liver was not cirrhotic, and we have no explanation for the greatly enlarged veins in the abdominal wall and greatly enlarged ovarian veins.

DR. BREED: What was the significance of the last statement? "Immediately afterward, it was noted that the skin of the face and chest was mottled."

DR. MALLORY: I do not know.

DR. BRAILEY: Could not caput medusae be due to venous tamponade?

DR. MALLORY: These vessels must have been dilated for a considerable period. I do not believe that the patient had cardiac tamponade for a long time before death. That amount of blood in the pericardium could not have been present at the time when the examiner reported the area of the cardiac dullness as normal in size.

DR. FREMONT-SMITH: In 1939, my record states that one vein below and leading to the umbilicus was distended.

DR. BREED: Did the esophagus show anything?

DR. MALLORY: There was no stricture. There was a colloid goiter, with cystic degeneration, and it is possible that pressure from the goiter may have caused esophageal obstruction.

DR. EDWARD F. BLAND: I do not recall seeing or having read of pain in the ear with dissecting aneurysm.

DR. MALLORY: Coronary pain occasionally goes to the ear. We had one patient here who nearly had his mastoid process opened for coronary thrombosis.

A PHYSICIAN: Was the brain examined?

DR. MALLORY: Yes; it was normal.

## CASE 28112

## PRESENTATION OF CASE

*First admission.* A seventy-five-year-old German-American retired store owner was admitted to the hospital because of weakness.

He was in good health until about four months before entry, when there was gradual onset of weakness, dyspnea and a sense of pressure in the chest on effort. He had little palpitation, but no pain or orthopnea. His appetite was fair until three days before entry, when he experienced some eructation and some diarrhea, with cramps. There were no other gastrointestinal symptoms.

The family history was irrelevant. The patient had been admitted to the hospital two and a half years earlier because of a tender mass be-

neath the left nipple. A simple mastectomy was performed, a biopsy showing chronic cystic mastitis. At that time, examination of the blood showed a red-cell count of 2,600,000 with 65 per cent hemoglobin. Since this admission, the patient had lost about 30 pounds in weight.

On examination, the patient appeared pale and emaciated. His tongue was neither smooth nor red. The fingernails were flat, with longitudinal ridges. The veins over the costal margins and upper thorax appeared quite prominent. The lungs were normal. The heart was of normal size, with a faint systolic murmur at both base and apex. The abdomen was normal, except for bilateral inguinal hernias. Vibration sense and position sense were present, but diminished in the feet.

The temperature, pulse and respirations were normal. The blood pressure was 145 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 4400 with 36 per cent polymorphonuclears and 64 per cent lymphocytes, and a red-cell count of 1,910,000 with 45 per cent hemoglobin and a color index of 1.28. The cell volume was 20.7 per cent, with a volume index of 1.28. The red cells showed macrocytosis; there was a reticulocytosis of 0.6 per cent. The blood Hinton reaction was negative. The Takata-Ara and formol-gel reactions were negative. The serum protein was 5.8 gm. per 100 cc. The van den Bergh reaction was normal. The bromsulfalein test showed normal excretion of dye.

Examination of the urine at admission showed a + test for albumin, and 200 red blood cells per high-power field in the sediment. A few colonies of *Staphylococcus albus* were obtained on culture; four subsequent studies of the urine showed 17 to 25, 10 to 15, 0 and 0 red blood cells, respectively. Examination of the stools was negative. Examination of the stomach contents showed no free acid after histamine.

Roentgenographic examination of the esophagus, stomach and duodenum was negative. An intravenous pyelogram showed good excretion of dye and normal pelvis, but the calyces were obscured by intestinal shadows.

The patient was treated with six successive experimental liver-extract fractions, over a period of three months, with only minimal improvement in the blood picture. There was some relief of the weakness, however. At discharge, examination of the blood showed a red-cell count of 2,940,000 with 71 per cent hemoglobin, 33.6 per cent cell volume and 1.8 per cent reticulocytes.

*Final admission* (one and a half years later). The patient was followed in the Out Patient De-

partment and was given the usual course of intramuscular treatment with a standard commercial liver extract. Roentgenologic examination of the upper gastrointestinal tract was negative on two occasions. The red-cell count ranged between 3,000,000 and 4,400,000, until a few months before re-entry, when it slowly fell to 2,400,000 despite maintenance of regular liver extract. One week before re-entry, the patient became quite weak and drowsy, and yet was unable to sleep. He also developed increasing dyspnea on exertion, anorexia and nausea, and complained of a "brown taste" in his mouth.

On re-examination, he appeared pale, but well nourished. There was frequent stuttering, and nervous twitching. The lungs seemed emphysematous, with fine inspiratory rales at the right base posteriorly. The heart was of normal size, with a loud systolic murmur over the precordium. The veins over the upper thorax were dilated. There was pitting edema of the legs. The abdomen appeared as before. The reflexes were hyperactive, with a questionable Chvostek sign. Vibration sense was slightly diminished in the lower extremities.

The temperature was 98°F., the pulse 75, and the respirations 25. The blood pressure was 190 systolic, 90 diastolic.

Examination of the blood showed a white-cell count of 9200 with 67 per cent polymorphonuclears, and a red-cell count of 2,940,000 with 68 gm. hemoglobin, 28 per cent cell volume, a color index of 0.78, 0 per cent reticulocytes, and numerous macrocytes. The nonprotein nitrogen was 138 mg. per 100 cc.

Examination of the urine showed a ++++ test for albumin, and a sediment with 10 red cells, 2 or 3 white cells and a few finely granular casts per high-power field.

A roentgenogram of the chest showed a picture consistent with pulmonary edema on the right side.

The patient received supportive treatment, but failed rapidly. On the third hospital day, the temperature rose to 101°F., the pulse to 102, and the respirations to 35. The patient expired, apparently in uremia.

#### DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: If there were any surgical brethren here, I should have asked them if it is customary to discharge patients with severe anemia without doing anything about it. I do not see anyone here to ask about that problem. Certainly, a man with a red-cell count of 2,600,000 requires a little thought concerning the cause of that anemia.

I might add that the mean cell volume figures

out at 108 cubic microns, macrocytic by measurement and macrocytic by observations, as it says in the next sentence, "The red cells showed macrocytosis."

There is nothing in the story of the first admission to suggest any diagnosis but pernicious anemia. The original symptoms, those of weakness, dyspnea and a sense of pressure in the chest, could well have been due to anemia alone, although we must remember that they could also have been caused by some degree of coronary disease or coronary occlusion.

The physical examination is perfectly consistent with a diagnosis of pernicious anemia, although there is nothing particularly corroborative about it. The flat fingernails with longitudinal ridges may not be of significance. They may indicate a nutritional deficiency in a rather elderly man. The fact that the vibration sense was present does not rule out the diagnosis of pernicious anemia. Diminished vibration sense in elderly people is of no diagnostic significance. In fact, it is difficult to use the vibration sense as a criterion of disease in such patients. The blood picture shows a macrocytic anemia, although not very highly macrocytic by count, if the counts are correct. The color index is high, higher than the mean cell volume indicates, and suggests that one of these two figures is incorrect. I think we can take it that the patient had a macrocytic anemia.

In an attempt to explain the urinary findings, an x-ray examination with intravenous pyelogram was done.

I am assuming that this patient had pernicious anemia, in addition to something involving the genitourinary tract that resulted in hematuria.

Have we any of the x-ray films?

Dr. TRACY B. MALLORY: Yes; we have a film, but no radiologist is here to interpret it.

Dr. RICHARDSON: I must confess that I cannot make much out of it. I can see filling on one side but not on the other. I shall not say anything more about it, but hope that one of the experts will be here before I have finished.

Another thing in the record that I think it fair to ask for and discuss is the specific gravities of the urine on the occasions when it was examined.

Dr. J. H. MEANS: I find one specific gravity of 1.022 on the first admission, and at the second admission, it ranged from 1.020 to 1.022.

Dr. RICHARDSON: It is of some importance and some interest that the specific gravity was 1.022 at the first admission.

The question of the diagnosis of pernicious anemia depends somewhat on the terminology. If one accepts as a criterion for the diagnosis the

fact that anemia is subsequently relieved by liver extract, one has a rather broad group of cases that can be called pernicious anemia. The diagnosis of pernicious anemia may be limited to a group that is due purely to some possibly congenital defect of the gastric mucosa resulting in a deficient secretion of gastric juice—so-called "idiopathic" or "agnogenic" Addisonian pernicious anemia. Furthermore, one must consider a characteristic group of pernicious-anemialike cases relieved by liver extract that are due to secondary disease elsewhere. As we go on in this case, however, if we assume that it is pernicious anemia, there is nothing to suggest any underlying disease that might produce pernicious anemia in a secondary manner.

"The patient was followed in the Out Patient Department and was given the usual course of intramuscular treatment." The usual course of intramuscular treatment was not the correct one. If the total red-cell count could not be maintained at a level of 5,000,000, he should have had an unusual course of treatment involving much larger amounts of liver. Nevertheless, there was an apparent definite response, which suggests that the diagnosis of pernicious anemia may well have been correct.

"The veins over the costal margins and upper thorax appeared quite prominent." I think that is a red herring and I shall say no more about it.

On the second entry, the quality of the anemia changed from a definitely macrocytic to a probably microcytic one, and also probably slightly hypochromic. This man had pernicious anemia, and was thoroughly treated. It is a fairly safe diagnosis for me to make because I do not believe that Dr. Mallory can check me up on it. If the patient had pernicious anemia that was not thoroughly treated, he can check me on it, but I do not see how I can lose either way. If he says that the anemia was due to some other disease, I shall counter that by saying that the change in the anemia may have been due to some other disease.

I want to mention the cystic mastitis and raise the question whether the patient had carcinoma of the breast, with widespread metastases and some involvement of the urinary tract. That seems a wild guess to make. There is no suggestion of bone-marrow replacement from the appearance of the smear, by x-ray study or by symptoms. The first thing I considered as a cause of the urinary findings and uremia was urinary obstruction. Did the patient have an enlarged prostate, with simple retention and uremia from retention? The rectal examination, I assume, was negative, and there was no evidence of bladder

enlargement; it seems unlikely that that could have been the cause of the anemia. With pernicious anemia, one must think, of course, of cord bladder, but there is no suggestion of cord involvement and I think we should rule that out. If there was obstruction, it must have been ureteral and due to tumor. That seems a rather far-fetched idea to me. The commonest cause of recurring hematuria in an elderly patient with fairly normal specific gravity is some vascular disturbance in the kidney, either repeated embolus to the kidney or nephrosclerosis of the kidney. What seems to me most probable is that this patient had rather marked generalized arteriosclerosis, which involved the kidneys more than other organs, and that the renal findings were due to a form of nephrosclerosis. It also seems probable that there was involvement of the coronary vessels, but not very marked.

One other possibility is that this patient developed pericarditis. Frequently, Dr. Mallory finds acute pericarditis that has not been suspected by the clinicians. The facts that this man's temperature rose rapidly and that he died so quickly suggest that there may have been something superimposed, and one could bring up the question of pericarditis. I see nothing to suggest it definitely.

I have left out one disease that one should always think of in the presence of anemia and uremia—plasma-cell myeloma. I considered this very strongly, but the urinary findings do not seem consistent with nephrosis. They were not those of the plugged-tubule type of renal failure, since there was too much hematuria. Also, the type of anemia was not that usually seen with bone-marrow encroachment by neoplasm in that there was not enough evidence of immature red cells or of active bone-marrow regeneration, so that I rule out myeloma on these two counts.

That leaves me with the diagnosis of pernicious anemia, which was probably not a factor in the patient's death, and generalized arteriosclerosis, more marked in the kidneys, and resulting in nephrosclerosis, uremia and death.

DR. JACOB LERMAN: I should like to ask about the pulmonary edema.

DR. RICHARDSON: I wondered about the unilateral pulmonary edema, and wondered whether I should have dismissed the question that this breast condition was a carcinoma after all.

May I see the x-ray film again? I did not visualize any picture such as that. It makes me feel badly.

DR. MALLORY: Dr. Richard Schatzki and Dr. A. Thornton Scott, a couple of years ago, noted focal pulmonary edema quite similar to this in a

number of patients with nephritis and usually with uremia.

DR. ALFRED KRANES: Dr. M. C. Sosman has also collected an interesting group of cases of unilateral edema and of one-lobe pulmonary edema in heart failure; these cases presented the most striking pictures that I have seen.

DR. RICHARDSON: One of my rules is not to change my mind at the last moment. I am not going to now.

DR. MALLORY: Dr. Means, have you anything to add?

DR. MEANS: We made clinically about the same diagnosis that Dr. Richardson did. I think there is no more to be said about that.

I am interested in the x-ray picture. I was thinking of Dr. Schatzki and Dr. Scott's observations and also the demonstrations that Dr. Frank Fremont-Smith made a number of years ago that edema in general is closely related to body position. It would be interesting to take pictures of such patients, having them lie for a while first on one side and later on the other to see if the picture changed. It is a new concept to find edema in the middle of the lung field, and it may be because the patients are lying down, and hence this area may be the dependent portion.

DR. MALLORY: I shall disagree with that in a moment.

DR. LERMAN: This patient had a hematuria of 200 red cells in the first sediment. That seems to be a good deal for mere vascular disease of the kidney. I am rather inclined to some malignant process in the bladder or in the kidney itself.

DR. RICHARDSON: I think that hematuria occurs either with embolism or with vascular disease. I certainly have seen it.

#### CLINICAL DIAGNOSES

Pernicious anemia.

Uremia.

Pulmonary edema.

#### DR. RICHARDSON'S DIAGNOSES

Pernicious anemia.

Nephrosclerosis, with uremia.

#### ANATOMICAL DIAGNOSES

Subacute glomerulonephritis.

(Pernicious anemia.)

Focal pulmonary hemorrhage.

Bronchiectasis, right middle lobe.

Arteriosclerosis, moderate, aortic and coronary

Hypertrophy of the heart.

Operative scar: left mastectomy.

Inguinal hernias, bilateral.

## PATHOLOGICAL DISCUSSION

DR. MALLORY: The autopsy showed primary disease of the kidneys, which weighed 275 gm. and were rather pale. The surfaces were still fairly smooth, with beginning granulation. The microscopic examination showed a subacute or very early chronic glomerulonephritis. How long the patient had it, it would be difficult to estimate on histologic grounds alone; I should think that it was not over a period of two years. It developed some time between the mastectomy and either the first or the second subsequent admission. Whether he had it at the first re-entry, I cannot be sure.

The heart was slightly hypertrophied. The coronary arteries showed atheroma, but no point of occlusion. The lungs showed focal bronchiectasis and also a lesion that we have seen a number of times in nephritis and to my eye is indistinguishable from what we occasionally see in cases of acute rheumatic fever. It has been described clinically as pulmonary edema, but under the microscope it is predominantly pulmonary hemorrhage. There are almost always foci of organization by connective tissue, which are usually found in the respiratory bronchioles. Many of these cases could be and, I believe, sometimes

have been described as bronchiolitis obliterans. It is certainly not pulmonary edema such as one sees in the average cardiac patient. The alveoli are full of red cells; there is a moderate amount of fibrinoid material, usually at the periphery. Usually, there are no leukocytes. To my eye, it is as yet indistinguishable from what has been described as rheumatic pneumonia.

The bone marrow is the only thing that could possibly substantiate or deny Dr. Richardson's diagnosis of pernicious anemia. I do not consider it very conclusive. It was rather more hyperplastic than the marrow of chronic nephritis usually is, with a distinctly greater degree of proliferation of the red cells than is seen in the average case of nephritis, not a clearcut picture of pernicious anemia. On the other hand, the alterations from what one ordinarily meets in chronic nephritis were definitely in the direction of pernicious anemia. Consequently, I am inclined to think it did show some effect of that disease as well.

DR. MEANS: Are you suggesting that the findings that Dr. Schatzki and Dr. Scott described as edema were not edema?

DR. MALLORY: Yes.

DR. MEANS: That is all right then. You can fight that out with Dr. Schatzki and Dr. Scott.

## A CHANGE IN THE BOARD OF REGISTRATION IN MEDICINE

ON February 17, 1942, Dr. Stephen Rushmore resigned from the position of secretary of the Massachusetts Board of Registration in Medicine to accept the position of dean of the School of Medicine of Middlesex University. Governor Saltonstall has appointed Dr. H. Quimby Gallupe, of Waltham, to fill the vacancy, and on February 26, at a meeting of the Board, Dr. Gallupe was elected secretary. As secretary, Dr. Gallupe has three additional *ex-officio* positions: he is chairman of the Approving Authority for Colleges and Medical Schools and secretary of the Board of Registration of Nurses and of the Approving Authority for Schools of Nursing.

As the holder of these various positions, Dr. Gallupe will be faced with many important problems. One of the most difficult is a decision that must sometime be made by the Approving Authority for Colleges and Medical Schools. It is well known that two medical schools and one osteopathic school in Massachusetts are not approved by their respective national societies; however, no public statement concerning their status, even in part, has been issued by the Approving Authority. Since this law went into effect in 1941, all members of the present first-year classes of these schools are receiving a medical education that may prove to be futile, and it seems likely that an embarrassing situation will arise. If the eventual decision is adverse, the students will feel aggrieved, and justly so, that the judgment—at least that covering their years of attendance—had not been passed sooner. If the decision is favorable, some people will undoubtedly question the legality of a retroactive verdict in such a situation, claiming that only the part of the students' education should be recognized that occurred after the decision had been made. It is apparently the clear intent of the law that, from its effective date of operation, no medical education shall be considered valid unless it has been gained in an approved school.

Dr. Gallupe's experience and training, not only in the practice of medicine but also in the affairs of the Massachusetts Medical Society, are such that the public and the profession can have confidence in those boards of which he is now an influential member. The Governor, the Governor's Council and the Board of Registration in Medicine are to be congratulated on having made an excellent appointment to a very responsible position.

## CIVILIAN DEFENSE

OUR country, long before the attack on Pearl Harbor, had begun to realize the necessity for civilian defense. Air-raid wardens were in training, the versatility of the triangular bandage was

a matter of tea-table discussion, new and strange feminine uniforms had made their appearance, and Red Cross headquarters in every direction hummed like sawmills. Despite our own relative insularity, we were aware that events were stirring. We knew, secretly, that "it couldn't happen here," but we almost wished that it could, in a mild sort of way, so that we might show how America handled these things.

And then came Pearl Harbor, like a rash and a fever, and we knew that we, too, had the epidemic disease; we were a nation at war. For those who were unable, by reason of age, sex or other incapacity, to join the armed forces, some other quick emotional outlet was necessary; the important thing was to rally in some way to the country's defense—to be doing something.

As a result of this enthusiastic and heartening response, civilian defense has come a long way toward becoming an effective organization: an organization that will, we trust, have little occasion to be used, but one whose serious existence is absolutely mandatory. Committed to this work are our air-raid wardens, our auxiliary fire departments, our lonely watchers of the midnight skies and, above all, those necessary defenders of the commonweal who daily fight the battles of the committees.

There is some vitally essential activity for every individual to share, in addition to paying his taxes and buying defense bonds, but it might be well to remind ourselves, occasionally, that these cannot all be dramatic or obviously heroic activities. We are engaged now in a race toward a goal of production. If we win it, democracy may yet be saved; if we fail, the future looks dismal enough. As impressive as the most military of our civil uniforms and far surpassing them in numbers must be the aprons and the overalls.

When the first-aid fever has died down a bit, when the last sacroiliac strain, the result of over-zealously applied artificial respiration, has been

strapped, when the last broken rib has mended and when the last breathless housewife has received her certificate, we may recall the sober fact that not one in a thousand of our first aiders will ever have occasion to adjust a traction splint or save a life by applying a skilful finger to a pressure point, but that everyone who has taken the equivalent course in nutrition or home nursing will probably have plenty of opportunity to employ the knowledge gained before the year is out. This war will be won by having the greatest number do that for which there is the greatest need and by having each willing to perform faithfully that service for which each is best fitted.

## MEDICAL EPONYM

MURPHY DRIP

Dr. John Benjamin Murphy (1857-1916) spoke on "Diffuse Suppurative Peritonitis" before the American Association of Obstetricians and Gynecologists on September 21, 1906. His remarks included some mention of his new method of proctoclysis, and in the subsequent discussion he described it as quoted below from the *Transactions of the American Association of Obstetricians and Gynecologists* (19: 184, 1906):

An ordinary vaginal douche tip should be used, with three openings, so that the water can flow into one and the intestinal gas come out of the other. If we use a single opening tip, gas will not bubble back into the can, and the passing of gas is important, otherwise the fluid will be expelled in the bed when the patient attempts to pass the gas. The elevation of the can should be from four to six inches above the anal level. The nurse must be instructed to watch the patient closely and not allow any more than one pint and a half of the saline solution to flow in forty minutes to one hour. The tube can be strapped permanently to the leg of the patient with adhesive plaster, the fountain syringe being at the head of the bed, and a hot water bag used to keep the solution warm. Every two hours the nurse pours in hot saline water. There is no irritation of the rectum. The patient may go to sleep while the irrigation is being carried on, as the tube is not taken out for days. It is merely absorption of the fluid by the bowel. The speed of the flow must not be controlled by a forcep in the tube, but by the elevation of the can.

## MASSACHUSETTS MEDICAL SOCIETY

## COMMITTEE ON MATERNAL WELFARE\*

CASE HISTORY: COMPLETE SEPARATION OF  
PLACENTA, FOLLOWED BY DEATH

A thirty-eight-year-old para V called her physician because of some bloody discharge when she was about seven months pregnant. The previous history was irrelevant; the patient had had no serious illnesses. Her four previous pregnancies and deliveries had all been normal.

She was first seen during this pregnancy when about three months along and went to her physician every four weeks thereafter until the onset of the present complication. The blood pressure and urine were reported to be normal, there had been no edema, and the blood Wassermann reaction was negative. There had been an interval of four weeks between the last visit and the onset of symptoms. On examination, the abdomen was boardlike. The amount of external bleeding was very slight. The patient was immediately sent to the hospital, where she arrived one and a quarter hours later. The fetal heart was not heard. The blood pressure on entry was 66 systolic, 40 diastolic, but later rose to 150 systolic, 90 diastolic. A transfusion was immediately given. Vaginal examination showed that the patient was not in labor. A Spanish windlass was applied. The membranes were not ruptured. The cervix and vagina were not packed. No other treatment was instituted, and death occurred six hours after admission. No autopsy was performed.

*Comment.* This is a typical case of complete premature separation of the placenta. It is quite probable that during the month between the last visit and the onset of bleeding, this patient's blood pressure rose and albumin appeared in the urine. The fatal outcome emphasizes the need of more frequent urinalyses and prenatal visits in the last trimester of pregnancy. The blood pressure on admission shows that this patient had bled tremendously inside the uterus and was in a very serious condition. The treatment can be criticized only in that the membranes were not ruptured and that there was no cervical or vaginal packing. Abdominal deliveries on patients with completely separated placentas who are in such poor condition as this patient was, are but adding insult to injury and are not advisable. Such fatalities can be prevented only by more intelligent co-operation between patient and physician and more frequent prenatal visits and urinalyses after the seventh month.

\*A series of selected case histories will be published weekly. Comments and questions by subscribers are solicited and will be answered by members of the committee. Letters should be addressed to the secretary, Dr. Raymond S. Titus, 330 Dartmouth Street, Boston.

## DEATHS

**HARTWELL** — **WILLIAM W. HARTWELL, M.D.**, of Malden, died March 1. He was in his sixty-ninth year. Born in Woburn, Dr. Hartwell received his degree from Harvard Medical School in 1900. He served as city physician in Malden for several years and as medical examiner of the Malden Board of Health. He was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by two sons.

**REED** — **VICTOR A. REED, M.D.**, of Methuen, died February 24. He was in his seventy-fourth year.

Born in Dixmont, Maine, the son of William E. and Elizabeth Ferguson Reed, Dr. Reed completed his preparatory education at the Hampden High School and studied for two years at Colby College in Waterville, Maine. He received his degree from Harvard Medical School in 1897 and did postgraduate work at the New York Polyclinic Medical School and Hospital.

Dr. Reed served as a line officer in the National Guard in 1902 and later as a captain in the Medical Corps at Fort Williams, Portland, Maine. He was a member of the staff of the Lawrence General Hospital, and was a former medical examiner for the fifth Essex district. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, Mrs. Josephine B. Reed, and a daughter, Mrs. J. Alexander McWilliams, of Chicago.

## WAR ACTIVITIES

## SELECTIVE SERVICE SYSTEM

## PHYSICAL REHABILITATION PROGRAM

Tests of a physical rehabilitation program, intended to make many registrants who were rejected because of minor physical defects fit for active military service, have been authorized in Maryland and Virginia, according to a recent release from the National Headquarters, Selective Service System. Authorization of the rehabilitation programs in the two states marks the beginning of a long-planned nation-wide physical rehabilitation campaign. When the results of these pilot tests are evaluated, a date for the inauguration of the inclusive program will be set. Only those registrants whose disabilities are certified by the Army as being remediable will be eligible to undergo treatment.

As one of the first steps in the Maryland and Virginia test programs, the director of Selective Service System in each state will submit to National Headquarters lists of physicians and dentists qualified to correct physical defects of registrants. Physicians and dentists designated to render these authorized professional services will be paid by the federal government. Any physician or dentist may apply to be included in the rehabilitation program and can obtain the necessary application form from his local board.

## CORRESPONDENCE

"THE POLITICAL LIFE OF THE  
AMERICAN MEDICAL ASSOCIATION"

*To the Editor:* Just before Christmas, I received a catalog from the Harvard University Press. One item listed therein particularly caught my eye — *The Political Life of the American Medical Association*, by Oliver Garceau, instructor in government at Harvard. I bought a copy, and have just finished reading it. Having found it highly

interesting informative and possibly important, I decided to see what reviewers had to say about it. I first encountered the contribution in the Book Reviews column of your issue of January 1. I must confess that I was taken aback by the ineptitude of this statement. It is hardly a review of Mr Garceau's book. It is rather a blanket condemnation.

Your reviewer applies various derogatory adjectives of which jejune is perhaps the prize. Jejune, like jejunum comes from the Latin *jejunus*, meaning empty, dry or barren and, in my opinion, is applicable to your so-called review but not at all to Mr Garceau's book, which, whatever else it may be, is certainly not empty, dry or barren.

Your reviewer also accuses Mr Garceau of having such a biased point of view that it takes away any force that he might have in argument. This accusation strikes me as preposterous. The work is not an argument, it is simply an analysis by a student of government of a politico-social phenomenon of some prominence. It discovers many good features, as well as some bad ones in organized medicine. There is no reason on earth why a student of government, or politics, should have any bias about such a matter, nor could I find in his book any evidence that he has. I, for one, am convinced that his approach is thoroughly objective, and that his facts are probably approximately correct. I do not know him, but that is the impression that I get from reading his book.

It seems to me that what your reviewer has chiefly succeeded in doing is to disclose himself as the biased one, not Mr Garceau. I do not know who he is but I should guess that he is one of those 'stalwarts' of organized medicine whom Mr Garceau identifies as believing that the layman is unfit to have an opinion in medical matters and extends this value judgment to include medical politics and medical economics, fields where it might almost be said the doctor is inherently unfit.

Differing diametrically from your reviewer on the merit of Mr Garceau's work, I should like, through your correspondence column to offer to the members of our profession, advice opposite to his, namely, that they read this book and form their own opinion of it afterwards.

## BOOK REVIEW

*The Foot and Ankle. Their injuries, diseases, deformities and disabilities with special application to military practice.* By Philip Lewin, MD. Second edition. 8°, cloth 660 pp., with 304 illustrations. Philadelphia: Lea and Febiger, 1941. \$9.00.

From the publishers' point of view, this second edition of Philip Lewin's book on the foot and ankle is admirably done although somewhat awkward to handle. One wonders what would happen should the author ever be tempted to write a textbook on orthopedic surgery. Six hundred and eighteen pages on the foot and ankle alone could hardly escape being a mere repository for the gleanings of an encyclopedic mind. No one can deny that the work has not been most thoroughly done.

So many new surgical procedures have come out and are continually being added to, that scarcely any of them have had time enough to warrant their acceptance or rejection. Kridas's operation (page 176) for metatarsalgia is a case in point. If one wishes a reference book in which is enumerated almost every kind of treatment

that has been proposed, without critical consideration of its applicability, this volume is the one to buy. The experienced orthopedic surgeon may be trusted to recognize what procedures are feasible, but to the young and inexperienced, something more is needed than a catalogue of the ships. Had the author drawn on his wide clinical experience to aid the audience he is addressing through this volume in selecting the tried and proved techniques, he would have rendered a greater service and done so in much less space.

## Erratum

In the review of the book *Oral Pathology. A histological, roentgenological and clinical study of the diseases of the teeth, jaws and mouth*, which appeared in the February 19 issue of the *Journal*, the authors were listed as Kurt H Thoma, DMD and Charles A Brackett, DMD. The author is Dr Thoma, who is professor of oral surgery and Charles A Brackett Professor of Oral Pathology, Harvard University.

## NOTICES

### TUFTS COLLEGE MEDICAL SCHOOL ALUMNI ASSOCIATION

Dr Frank H Lahey, president of the American Medical Association, will be the guest speaker at the annual Tufts College Medical School Alumni Dinner, at 7 p.m. on Wednesday, March 23, at the Hotel Somerset. His subject will be *The Doctor's Place Today*. Dr James W Manary, superintendent and medical director of the Boston City Hospital will preside.

Other speakers on the program are Dr A K Paine, president of the Alumni Association who will discuss the Association's activities; Dr Leonard Carmichael, president of Tufts College, who will report on the medical school fund; Dr Priscilla White, who will speak on *The Woman Physician*; Dr Frank R Ober, who will extend the greetings of the Massachusetts Medical Society; and Dr Roy J Heffernan, who will speak on *The Twenty Five Year Class*.

The dinner will be preceded by a business meeting at 6.15 p.m.

### ROBERT DAWSON EVANS MEMORIAL LECTURE

Dr William Dock, professor of pathology at Cornell University Medical College, will give the Robert Dawson Evans Memorial Lecture on Friday, March 27, at 8.15 p.m. in the Evans Memorial Auditorium, 78 East Concord Street, Boston. His subject will be *Albuminuria and Associated Renal Changes*.

Physicians and medical students are cordially invited to attend.

### BOSTON LYING IN HOSPITAL

A meeting of the Journal Club of the Boston Lying in Hospital will be held in the lecture hall of the hospital on Wednesday, March 18, at 8.15 p.m. Dr Robert E Gross will speak on *Surgical Problems of the Newborn*.

Physicians and medical students are cordially invited to attend.

### CARNEY HOSPITAL

The monthly clinical meeting and luncheon of the Carney Hospital will be held in the hospital auditorium on Monday, March 16 at 11.30 a.m.

## PROGRAM

Use of Spinal Anesthesia in Obstetrics. Dr. Joseph Ferrone.

Treatment of Hydrocephalus in Obstetrics, with Report of a Case. (With Films.) Dr. Arthur Gorman.

Rupture of Uterus. (With Films.) Dr. Cornelius T. O'Connor.

Physicians and medical students are cordially invited to attend.

## MASSACHUSETTS GENERAL HOSPITAL

A meeting of the Hospital Research Council will be held in the Bigelow Amphitheater of the White Building on Tuesday, March 24, at 5 p.m.

## PROGRAM

Effects of Rebreathing on Sighing Respiration and Anxiety Symptoms in Patients with Anxiety Neurosis. Drs. S. Cobb and M. Cohen.

Rheumatic Fever and Heart Disease: Special clinical features from a completed ten-year study of 1000 patients. Drs. E. F. Bland and T. D. Jones.

An Epidemic of Rheumatic Fever. Dr. T. D. Jones.

## NEW ENGLAND ROENTGEN RAY SOCIETY

A meeting of the New England Roentgen Ray Society will be held in John Ware Hall, Boston Medical Library, on Friday, March 20. There will be an x-ray conference from 4:30 to 6:00 p.m., followed by a round-table discussion on radiation therapy, conducted by Dr. Frederick W. O'Brien. At 8:00 p.m., the following program will be presented:

Sarcoid and Erythema Nodosum. Drs. Charles A. Janeway, Orville T. Bailey and Merrill C. Sosman.

Periarteritis Nodosa and Lupus Erythematosus Disseminata. Drs. Eugene A. Stead, Orville T. Bailey and Merrill C. Sosman.

Discussion. Drs. Chester S. Keefer, Tracy B. Mallory and Aubrey O. Hampton.

## NEW ENGLAND PATHOLOGICAL SOCIETY

There will be a meeting of the New England Pathological Society at the Peter Bent Brigham Hospital on Thursday, March 19, at 8 p.m. The program will be presented by the Department of Legal Medicine of the Harvard Medical School.

## PROGRAM

The Law and the Pathologist. Dr. Hubert W. Smith.  
An Experimental Study of the Chemical Changes which Occur in the Blood as the Result of Death by Drowning. Drs. Walter W. Jetter and Alan H. Moritz.

Adaptive Intimal Changes which Occur in Arteries Following Localized Circulatory Stasis. Dr. Alan R. Moritz.

Medicolegal Tests for the Identification of Seminal Fluid. Dr. Otto J. Pollak.

An Experimental Investigation of the Stability and Distribution of Carboxyl Hemoglobin after Death, with Particular Reference to the Difficulties Sometimes Encountered in the Case of Incinerated Bodies. Dr. Herbert S. Breyfogle.

The Fauna of Putrefaction and Its Potential Usefulness in Establishing the Time of Death. Dr. J. C. Bequaert.

## MASSACHUSETTS TUBERCULOSIS LEAGUE

The annual meeting of the Massachusetts Tuberculosis League will be held on Thursday, March 26, at the Boston Sanatorium, Mattapan.

## PROGRAM

10 a.m. Round-Table Conference on Tuberculosis Programs in Boston. Drs. John A. Foley, Harry Goldman, James A. Keenan and Cleaveland Floyd, and the Misses Hazel Wedgwood and Dorothy Carter; Dr. George L. Gately, chairman.

11:45 a.m. Business meeting.

12:45 p.m. Luncheon.

2 p.m. Round-Table Conference on Tuberculosis Prevention through Readjustment as a War Service. Messrs. Arthur W. Gerness and John H. McFarland, Mrs. Mildred S. Jeynes, and Drs. William R. Martin and Frederick L. Bogan; Dr. Henry D. Chadwick, chairman.

The charge for luncheon will be 90 cents per person. Reservations should be sent to: Massachusetts Tuberculosis League, 1148 Little Building, Boston. Tel. HAN 5480.

## JEWISH MEMORIAL HOSPITAL

A diagnostic therapeutic conference will be held at the Jewish Memorial Hospital on Thursday, March 19, at 11 a.m. Dr. William P. Murphy will speak on "Blood Diseases."

Physicians and medical students are cordially invited to attend.

## NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

A regular meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore, Boston, on Wednesday, March 18, at 8 p.m. Colonel Winthrop Adams will speak on "Physical Medicine in Wartime." A council meeting will be held at 6 p.m., followed by an informal dinner in the Empire Room at 6:30 p.m.

All interested physicians are cordially invited to attend this meeting.

## EVANS MEMORIAL HOSPITAL

A research conference will be held in the auditorium of the Evans Memorial Hospital on Monday, March 23, at 5 p.m. Dr. Franz J. Ingelfinger will speak on "Studies on the Absorption Defect in Sprue."

## FEDERATION OF AMERICAN SOCIETIES FOR EXPERIMENTAL BIOLOGY

The Federation of American Societies for Experimental Biology will meet in Boston from March 31 to April 4. Registration will start on Tuesday, March 31, at 10 a.m. at the Hotel Statler. The headquarters, session dates and

## VITAMIN C AND WOUND HEALING\*

### I. Experimental Wounds in Guinea Pigs

MARSHALL K. BARTLETT, M.D.,† CHESTER M. JONES, M.D.,‡ AND ANNA E. RYAN, B.A.§

BOSTON

THAT the tensile strength of healing wounds is lowered in the presence of scurvy in guinea pigs was established by Lanman and Ingalls<sup>1</sup> in 1937 and confirmed by Taffel and Harvey.<sup>2</sup>

The work of Bessey<sup>3</sup> has provided a satisfactory method of determining the ascorbic acid content of tissues, and the experiments reported in this study were undertaken to determine the concentration of vitamin C in healing wounds in guinea pigs under a variety of dietary conditions, and to correlate the ascorbic acid content with the tensile strength of these wounds.

#### METHODS

After suitable dietary preparation, under ether anesthesia, a midline abdominal incision was made in each guinea pig, extending from the xiphoid to a point just below the umbilicus. A strip of tissue adjacent to the wound, consisting of the full thickness of the abdominal wall and weighing about 2 gm., was excised for ascorbic acid assay. This specimen is called "control tissue" in the various tables that appear below. The peritoneum and muscular layers were then closed in a single layer with a running suture of fine silk, and the skin was closed in a similar manner.

At the end of a suitable period of wound healing, the skin sutures were removed, and the healing wound excised, including the full thickness of the abdominal wall in a strip about 0.6 cm. in width, with the line of incision running down its center. This tissue was assayed for ascorbic acid and appears under the heading "abdominal scar" in the tables. Portions of abdominal wall adjacent to the excised scar and similar portions at a distance from it were removed for comparative assay.

These appear as "adjacent abdominal wall" and "distant abdominal wall" in the tables. Vitamin C determinations were also done on the livers and kidneys of these animals.

The term "house diet" is used to describe the usual one of grain, hay, green vegetables and water. As a scorbutic diet, we have found the one described by McCullough<sup>4</sup> most satisfactory. Animals can be successfully maintained on this diet for considerable periods. Its percentage composition is as follows:

Whole-milk powder (inactivated at 120°C. for two hours)	40.5
Ground, rolled oats	25.0
Bran	25.0
Dried brewer's yeast	5.0
Cod-liver oil	3.0
Sodium chloride	1.0
Ferric citrate	0.5

To afford a high intake of vitamin C, either the house diet or the scorbutic diet was supplemented by 33 mg. of ascorbic acid in 5 cc. of water twice daily. This solution was fed to the animals by medicine dropper and was usually taken without difficulty. The dosage is considerably larger than that reported by Zilva<sup>5</sup> and by Ecker and Pillemer<sup>6</sup> as necessary to maintain tissue saturation in the guinea pig, and should certainly provide an excess of ascorbic acid even in the presence of a possible increased demand due to the healing wound.

#### RESULTS

##### Control Animals

The ascorbic acid content of various animal tissues has been studied by several workers.<sup>7-15</sup> However, because of differences in methods of assay and varying experimental conditions, the results of these investigations are not strictly comparable to the studies reported here, and will not be referred to in detail.

\*From the Medical and Surgical services, Massachusetts General Hospital.

†Assistant surgeon, Massachusetts General Hospital.

‡Clinical professor of medicine, Harvard Medical School; physician, Massachusetts General Hospital.

§Technician, Massachusetts General Hospital.

To obtain control figures, the ascorbic acid content of the abdominal wall was determined on 19 guinea pigs on a scorbutic diet for two weeks or more. The average concentration was 0.23 mg. per 100 gm. Similar determinations were made on 17 animals on a high vitamin C diet for two weeks or more, and it was found that the average level was 1.51 mg. per 100 gm.

We believe two weeks to be an adequate period to establish a tissue level of ascorbic acid on a given diet. The results of assays of the abdominal wall, liver and kidney, made at intervals of one, two and three weeks, on animals on a high or low vitamin C intake appear in Table 1. There

seems to be no essential difference between the levels attained at the end of one week and those at longer intervals. We have therefore taken a period of two weeks as being adequate to establish tissue levels of ascorbic acid corresponding to the intake of vitamin C.

It is interesting that the house diet, which has apparently been entirely satisfactory over a period of years, and on which guinea pigs thrive for indefinite periods, produces tissue levels only slightly higher than the scorbutic diet. This wide variation in the amount of ascorbic acid necessary for protection against scurvy and that required to produce tissue saturation has been stressed by Zilva<sup>5</sup> and by Ecker and Pillemer.<sup>6</sup>

Experimental Animals

*Preoperative and postoperative scorbutic diet.* Ten guinea pigs were maintained on a scorbutic diet for two weeks. At the end of this time, an abdominal incision was made, and a control biopsy obtained. The scorbutic diet was continued postoperatively.

At the end of arbitrary intervals, varying from four to fourteen days, the animals were killed and tissue assays done, as previously described. The results of these determinations are shown in Table 2.

The average postoperative interval was nearly ten days, and there was no significant variation in

the tissue levels at the shorter and longer postoperative intervals. All the tissue levels were low, and the averages show that there was no increase in the concentration of ascorbic acid in the heal-

on a high ascorbic acid intake, 10 animals were subjected to the same operative procedure as that in the preceding group. At postoperative intervals of four to fourteen days, with an average of nine days, the animals were killed and the tissue assays of ascorbic acid were done. The results appear in Table 3.

Again, there was no significant difference in the results obtained at the shorter and longer post-

operative intervals. However, there was a marked increase in ascorbic acid content in the healing wound over the concentration in the control biopsy of the abdominal wall. The tissue of the abdomen

inal wall adjacent to the healing wound, taken at autopsy, showed a considerable increase in vitamin C content, and a slight increase was shown in the abdominal wall at a distance from the wound. The assays of liver and kidney showed levels uniformly much higher than those obtained on similar animals on a scorbutic diet, but not quite so high as those in the 3 animals on a high ascorbic acid diet on which no operation was done (Ta-

ble 1). The small number of animals in the last group makes it impossible to say whether or not this difference was significant. It seems unlikely, considering the very large doses of ascorbic acid administered to both groups.

*Preoperative scorbutic diet and postoperative high vitamin C diet.* It seemed desirable to study the relative importance of the preoperative diet and the ascorbic acid intake in the postoperative interval, in determining the ascorbic acid content of the healing wound and other tissues at autopsy.

Contrasting experiments were planned, one group of animals receiving a scorbutic diet preoperatively

*The photograph on the left shows the pressure required to separate the skin; that on the right, to rupture the wound.*

four to fourteen days seemed to make no significant difference in the tissue levels at autopsy.

on a high ascorbic acid intake both preoperatively and postoperatively. The extent of the rise was

somewhat less in each tissue in the group under discussion.

**Preoperative high vitamin C diet and postoperative scorbutic diet.** In contrast with the above group, 4 animals were maintained on a high ascorbic acid intake for two weeks before operation, and on a scorbutic diet during the postoperative interval. The results of the ascorbic acid assays on the various tissues appear in Table 5.

Although these animals were saturated with large amounts of ascorbic acid before operation, the tissue levels obtained at autopsy were strikingly similar to those of the group of animals on a scorbutic diet both before and after operation. Why one animal failed to show any ascorbic acid in the control biopsy of the abdominal wall, in spite of the high intake of ascorbic acid preoperatively, is not clear.

**Tensile strength and ascorbic acid content of healing wounds.** The work of Lanman and Ingalls,<sup>1</sup> establishing the decrease in tensile strength of healing wounds in the presence of scurvy, has already been mentioned. We have attempted to repeat this experiment, correlating the tensile strength of the healing wound with the ascorbic acid content of the healing scar.

Three animals were established on a scorbutic diet. Abdominal incisions were made and sutured in the manner already described. The same diet as maintained postoperatively. Another group of 3 animals was given a diet high in ascorbic acid throughout the experiment, and the same operative procedure was carried out.

Since our previous studies had indicated that ascorbic acid content of the healing wound is certainly stabilized ten days after operation, animals were killed at this time, and the tensile strength of the healing scar in the abdominal wall was determined by a method similar to that used by Lanman and Ingalls. An ordinary, long gauge needle was introduced into the peritoneal cavity, and connected by rubber tubing to a rubber bulb and sphygmomanometer (Fig. 1). Air was introduced into the peritoneal cavity until a pressure was attained sufficient to cause rupture of the wound. The pressure, recorded in millimeters of mercury, was noted.

Characteristically, the wounds ruptured in two places. Skin separation occurred at first, followed by higher pressure by the rupture of the muscular layer.

The ruptured wounds were then excised and assayed for ascorbic acid content. The results of this experiment appear in Table 6. The average tensile strength in the animals on a high ascorbic acid intake was exactly twice that of the animals on a scorbutic diet, and the vitamin C content of the healing wounds showed the same striking contrast already noted (Tables 2 and 3).

Figure 2 shows a typical wound in a scorbutic animal at the moment of rupture. In Figure 3, the rupture of a wound in an animal on a diet rich in vitamin C is shown.

### SUMMARY AND CONCLUSIONS

Wide variations of the ascorbic acid content of guinea-pig tissues, as measured by Bessey's method of tissue assay, can be caused by a high or low intake of ascorbic acid.

Similar variations of ascorbic acid content can be demonstrated in a healing wound of the abdominal wall, depending on the vitamin C intake.

Animals on a scorbutic diet show essentially no increase in ascorbic acid in the healing area and slightly lowered values in the remainder of the abdominal wall, compared with the level in control biopsies obtained at the time of operation. The liver and kidney also show low levels.

On a high ascorbic acid intake, a striking increase in vitamin C content of the healing wound over that of the control biopsy can be demonstrated. The abdominal wall adjacent to the scar also shows a considerable rise, and a slight increase is found even at a distance from the wound. High levels are also found in the liver and kidney.

In these experimental animals, the tissue level attained by the preoperative administration of ascorbic acid is of much less importance in establishing the optimum ascorbic acid content of the healing wound and other tissues studied than the vitamin C intake during the postoperative period.

The tensile strength of wounds showing a high ascorbic acid content is much greater than that of those with low vitamin C values.

## VITAMIN C AND WOUND HEALING\*

## II. Ascorbic Acid Content and Tensile Strength of Healing Wounds in Human Beings

MARSHALL K. BARTLETT, M.D.,† CHESTER M. JONES, M.D.,‡ AND ANNA E. RYAN, B.A.§

BOSTON

IN recent years, a considerable amount of evidence has established the efficacy of vitamin C in wound healing in animals. Lanman and Ingalls<sup>1</sup> first made direct measurements of the tensile strength of healing wounds in guinea pigs and found it decreased in the presence of scurvy. In the preceding paper,<sup>2</sup> we reported the results

a high ascorbic acid content was found to be much greater than that in those with low vitamin C values.

Elaborating on the work of Lanman and Ingalls, Taffel and Harvey<sup>3</sup> studied the effect of partial as well as absolute vitamin C deficiency on the tensile strength of healing wounds in guinea

FIGURE 1. Method of Obtaining Tissue for Ascorbic Acid Assay and Tensile-Strength Determinations.

1—incision through skin and subcutaneous tissue with excision of a strip of skin for ascorbic acid assay (K); 2—fascia stripped out in the usual manner for repair of the hernia, and for ascorbic-acid assay (L), with an incision made in the fascia lata for 2 cm. distal to the area stripped out; 3—incision in fascia closed with fine silk sutures; 4—skin closed in the usual manner.

of studies on the tissue ascorbic acid content of similar wounds in guinea pigs and correlated this with the tensile strength of these wounds. A much higher concentration of vitamin C occurs in the wounds of animals on a high ascorbic acid intake than in those of animals on a scorbutic diet, and the tensile strength of wounds showing

pigs. There was a slightly greater tensile strength at four days after operation in animals with absolute scurvy than in the normal controls. At six days, the tensile strength was markedly inferior to that in normal animals. None of the scorbutic animals survived for a longer postoperative period. In their experiments, a state of partial scurvy was established as follows: after a week on the scorbutic diet supplemented by 5 mg. of ascorbic acid daily, all vitamin C was withheld for two weeks, and then 0.2 mg. of ascorbic acid was given on alter-

§Technician, Massachusetts General Hospital.

the days. Abdominal incisions were made after 30 days on this low vitamin C intake. It is extremely interesting that, although all the animals showed unmistakable gross evidence of scurvy at autopsy, tests for tensile strength on the healing wounds showed a significant decrease below that of normal controls only on the eighth and tenth days after operation. Tests on the fourth and sixth days showed no appreciable variation from the controls, and those on the twelfth and fourteenth days again approached normal.

The effect of prolonged reduced intake of vitamin C on wound healing in an otherwise normal adult human subject has been studied by Cranston, Lund and Dill<sup>4</sup> and by Hunt.<sup>5</sup> In both studies, the histologic appearance of the wound

the same patient, followed by the administration of large doses of ascorbic acid, showed no macroscopic or microscopic difference from the first wound.

The present studies were undertaken in an attempt to obtain further information regarding the value of vitamin C in wound healing in human beings, by means of direct observations on the tensile strength of healing wounds and a correlation of these with the tissue content of ascorbic acid and plasma ascorbic acid levels.

#### METHODS

Male patients admitted to the hospital for the repair of inguinal hernias who were good surgical risks and on whom the use of fascia lata in

FIGURE 2. Method of Subsequently Obtaining Tissue for Ascorbic Acid Assay and Tensile-Strength Determinations.

*The skin scar is excised (M), exposing the healing fascial scar (N), which is also excised. The skin is then closed in the usual manner.*

was used as an index of abnormal healing. Cranston, Lund and Dill found that adequate wound healing occurred after the plasma ascorbic acid had been zero for forty-four days and when the white-cell and platelet ascorbic acid level was 4 mg. per 100 cc. A second wound, made when the plasma ascorbic acid had been zero for one hundred and forty-one days and the white-cell and platelet ascorbic acid content had been at zero for sixty-one days, failed to heal in a normal manner after ten days, and showed lack of intercellular substance and capillary formation on histologic examination. The intravenous administration of 1000 mg. of ascorbic acid daily for ten days brought about microscopic evidence of good healing. Hunt<sup>5</sup> reported histologic evidence of healing of an experimental wound in a subject who had been on a reduced vitamin C intake for three months and who had a blood ascorbic acid content of 0.34 mg. per 100 cc. A second experimental wound in

the repair was contemplated were selected for these studies.

During the preliminary period of two to four days, the plasma ascorbic acid was determined by the method of Mindlin and Butler,<sup>6</sup> and the daily urinary output measured by Bessey's<sup>7</sup> method. Throughout the hospital stay, these patients were maintained on a diet containing 100 mg. of vitamin C daily. Supplementary ascorbic acid was given to some patients before and after operation, as described in the case reports.

Studies were carried out on a total of 6 patients. Of these, 5 had unilateral hernias, and 1 had bilateral hernias.

The operations were performed under spinal anesthesia, and the usual hernia repair was done. Fascia lata was obtained through a longitudinal skin incision about 8 cm. in length just above the knee on the lateral aspect of the thigh. A strip of skin, weighing about 2 gm., was excised

from the edge of this wound for ascorbic acid assay as a control biopsy. The fascia was removed by means of a stripper, and in addition to that necessary for the hernia repair, enough was removed for ascorbic acid assay. The tissue ascorbic acid content was determined on the ex-

FIGURE 3. Method for Determining the Tensile Strength of Healing Scars in Skin and Fascia.

The apparatus consists of a 5-cc. glass syringe, with collars mounted on the barrel and plunger (Aa and Bb). On each collar a bar is attached, pivoted at its center (A and B). Two pins (D), spaced 1 cm. apart, are mounted on each bar, and the tissue to be tested (M or N) is placed on these four pins. Tension is applied by weights on the platform. The pull necessary to rupture the scar is recorded in grams.

cised skin and fascia by the method described by Bessey<sup>7</sup> and previously employed in our animal experiments. Distal to the area of excised fascia, a longitudinal incision 2 cm. in length was made in the fascia lata, parallel to its fibers, and this was closed with interrupted sutures of fine silk. The skin was then closed in the usual manner with interrupted silk (Fig. 1).

The wound was allowed to heal for ten days, the skin sutures being removed on the eighth day. At the end of ten days, under novocain block anesthesia, the skin incision in the thigh was excised with a margin of slightly less than 1 cm. of skin on each side of the scar; the incision in the fascia was excised with the same margin of tissue (Fig. 2).

The tensile strength of the healing wound and the tissue ascorbic acid content were determined on the skin and fascia. In some cases, enough

skin was available to allow duplicate determinations. The tensile strength was measured by the application of a direct pull on the healing scar, as illustrated in Figure 3. The apparatus consisted of a 5-cc. glass syringe, with collars mounted on the barrel and plunger. Each collar carried a bar, pivoted at the center, bearing two pins spaced 1 cm. apart. The pivot provided an equalized pull on the tissue mounted on the pins, when tension was applied by means of weights placed on the platform.

As a result of duplicate determinations on portions of the same skin scars, it became evident that there was considerable variation by this method, and we believe that only gross differences should be considered significant.

### CASE REPORTS

CASE 1. A. A., a 65-year-old man, was admitted for repair of a right inguinal hernia. The plasma ascorbic acid was 0.60 and 0.66 mg. per 100 cc. on two occasions be-

FIGURE 4. Case 1.

Determinations of ascorbic acid in the blood plasma, in control biopsies of skin and fascia and in healing skin and fascial scars are shown. Urinary excretion of vitamin C is recorded in twenty-four-hour amounts, and the tensile strengths of the skin and fascial scars are listed. Where columns are superimposed, the actual amount of each component is the maximum height of the column above the abscissa.

fore operation, and no significant variation from this level occurred following operation.

Control biopsies of skin and fascia from the left leg were obtained at the time of herniorrhaphy. The skin

showed an ascorbic acid content of 2.49 mg, and the fascia one of 0.29 mg per 100 gm. At the end of 10 days, the skin and fascia scars were excised. The skin showed a tensile strength of 700 gm and a vitamin C content of 404 mg per 100 gm. The fascia scar broke at a tension of 1600 gm and contained 388 mg of ascorbic acid per 100 gm. The complete data on this patient appear in Figure 4.

CASE 2 E J L, a 36-year-old man, was admitted for repair of a left inguinal hernia. The preoperative plasma ascorbic acid was 0.20 mg per 100 cc on two occasions. Control biopsies of skin and fascia lata showed a vitamin C

FIGURE 5 Case 2

content of 0.99 mg and 0.48 mg per 100 gm, respectively. After healing for 10 days, the skin scar had a tensile strength of 4200 gm and an ascorbic acid content of 5.92 mg per 100 gm. The fascia scar ruptured at 1400 gm with a vitamin C content of 4.48 mg per 100 gm.

In this patient, except for a transient drop after operation the plasma ascorbic acid showed no significant variation during the postoperative interval. This transient fall has been previously noted by various workers. The studies on this patient are shown in Figure 5.

CASE 3 J S, a 24-year-old man, entered the hospital because of a left inguinal hernia. Two preoperative plasma ascorbic acid determinations showed 0.31 and 0.26 mg per 100 cc. Control biopsies of the skin and fascia lata were taken. The skin contained 0.84 mg and the fascia 0.11 mg of ascorbic acid per 100 gm. From the day of operation, 1000 mg of vitamin C was given daily in addition to the 100 mg contained in the regular diet. The plasma ascorbic acid level rose promptly and remained between 0.68 and 1.01 mg per 100 cc during the postoperative interval. A corresponding rise in urinary output of vitamin C occurred.

After healing for 10 days, the skin and fascia scars were excised from the leg. The skin scar had a tensile strength of 1500 gm and an ascorbic acid content of 5.23 mg per 100 gm. The healing fascia broke under a tension of 1200 gm, with a vitamin C tissue level of 7.65 mg per 100 gm. The complete data on this patient appear in Figure 6.

CASE 4 F W, a 62-year-old man, proved to be the most interesting patient studied. He had bilateral inguinal hernias, which were repaired separately. He also had the lowest preoperative plasma ascorbic acid level in the group—0.09 and 0.08 mg per 100 cc on two determinations. There was no clinical evidence of scurvy.

At the first operation the right hernia was repaired, and control biopsies of skin and fascia were obtained from the left leg. These tissues both showed a tissue ascorbic acid level of zero. No ascorbic acid, other than the 100 mg daily in the diet was given after operation, and the plasma ascorbic acid remained at the same low level.

At the end of 10 days, the left hernia was repaired, fascia from the right leg being used, and control specimens of skin and fascia were obtained from the new incision. They also showed a zero level of ascorbic acid. At the same

FIGURE 6 Case 3

time the 10-day-old scars in the skin and fascia of the left leg were excised. The skin scar had a vitamin C level of 0.67 mg per 100 gm and a tensile strength of 400 gm (average of two determinations). The healing fascia had a tissue level of ascorbic acid of zero and ruptured at a tension of 300 gm.

The patient was then given 1000 mg of ascorbic acid by mouth daily, in addition to that in the regular diet, and the blood ascorbic acid promptly rose to above 1.0 mg per 100 cc and remained at this level, with a corresponding increase in the urinary output of ascorbic acid.

Ten days after the second operation, the healing skin and fascia scars were excised from the right leg. An ascorbic acid assay on the skin gave a result of 6.77 mg.

FIGURE 7. Case 4.

*Tissue assay of vitamin C on the control biopsies of the skin and fascia at both operations and of the healing fascia excised at the second operation were all zero, and so do not appear.*

per 100 gm., and the scar separated with a pull of 1200 gm. (average of three determinations). The fascia contained 5.73 mg. of vitamin C per 100 gm., and the scar had a tensile strength of 1800 gm. Figure 7 shows the results of these studies in graphic form.

**CASE 5.** A.D., a 26-year-old man, was recommended for admission to the hospital because of a left inguinal hernia. The plasma ascorbic acid was found to be 0.26 mg. per 100 cc., and he was given 200 mg. of vitamin C daily for 2 weeks prior to admission. After a week, the plasma ascorbic acid was 0.98 mg. per 100 cc., and on admission it was 0.81 mg. The patient was given the same dose (200 mg.) of ascorbic acid daily in addition to 100 mg. in the diet, and on the day of operation the plasma ascorbic acid was 0.87 mg. per 100 cc. The hernia was repaired, and skin and fascia were obtained from the right leg for vitamin C assay. The skin contained 0.78 mg. and the fascia 0.17 mg. of ascorbic acid per 100 gm.

Except for the day of operation, when no ascorbic acid was given, the daily intake was maintained at a total of 300 mg. of vitamin C daily. Ten days after operation, the healing skin and fascia scars were excised from the leg. In addition, a small pigmented nevus was removed

from the back, together with a margin of surrounding normal skin.

The healing skin showed 5.54 mg. of ascorbic acid per 100 gm., and the scar ruptured with a pull of 600 gm. (average of three determinations). The fascia had a vitamin C level of 7.24 mg. per 100 gm. and a tensile strength of 1100 gm. The pigmented nevus was discarded, and the surrounding skin was assayed for vitamin C. A level of 1.88 mg. per 100 gm. was obtained. These studies appear in Figure 8.

**CASE 6.** T.D., a 48-year-old man, was admitted to the hospital because of a large left inguinal hernia. A plasma ascorbic acid determination 2 weeks before admission showed a level of 0.73 mg. per 100 cc. The patient was given 600 mg. of vitamin C daily, and this was continued, together with the 100 mg. in the regular diet, until 10 days after operation, except for the day of operation, when he received none. The plasma ascorbic acid was 1.26 mg. per 100 cc. on admission, and except for a transient

FIGURE 8. Case 5.

drop after operation, it remained above 1.0 mg. per 100 cc. until the supplementary dose of vitamin C was withdrawn.

At operation, the hernia was repaired with fascia from the right thigh, and control biopsies of the skin and fascia lata were obtained. The skin contained 1.63 mg. and the fascia 0.20 mg. of ascorbic acid per 100 gm.

After 10 days, the healing skin and fascia scars were excised from the leg. A pigmented nevus on the same leg, but at some distance from the healing area, was also excised, with a margin of normal skin. The healing skin

had an ascorbic acid content of 4.64 mg. per 100 gm., and the scar ruptured at a tension of 1600 gm. (average of four determinations). The fascia scar contained 6.79 mg of ascorbic acid per 100 gm. and had a tensile strength of 1700 gm. The skin surrounding the small pigmented nevus showed a vitamin C level of 1.10 mg. per 100 gm. These results appear in Figure 9.

### DISCUSSION

We have attempted to obtain information concerning the importance of vitamin C in wound healing in human beings by means of tissue ascorbic

comparable rise in ascorbic acid content and tensile strength is shown in spite of the variation in the preoperative plasma ascorbic acid from 0.20 to 1.19 mg. per 100 cc. In fact, in these 5 cases, the highest apparent tensile strength (2400 gm.) was found in the patient with the lowest preoperative plasma ascorbic acid (0.20 mg. per 100 cc.).

Except for Case 4, the ascorbic acid contents of the control biopsies of fascia were fairly consistent, varying from 0.11 to 0.48 mg. per 100 gm., with an average of 0.25 mg. Incidentally, this was considerably lower than the average vitamin C content of the control skin biopsies in these same patients, which was 1.35 mg. per 100 gm.

The healing fascia scar showed a marked rise in ascorbic acid content in every case, ranging from 3.88 to 7.65 mg. per 100 gm., with an aver-

FIGURE 9. Case 6.

acid determinations, contrasting the vitamin C content of ten-day-old healing scars in fascia and skin with that of control biopsies of these tissues obtained at the time the incisions were made. Direct tensile-strength determinations were also made on the healing fascia and skin scars.

In the healing of an ordinary abdominal wound, the strength of the fascia layer is of primary value, and we are particularly interested in the results of the determinations on this tissue. These data have been assembled for convenient study in Table 1.

With the exception of Case 4, we believe that there is no significant variation in the behavior of the healing fascia in the cases reported. A

age value of 6.01 mg. This is an average rise of more than twenty-four times the control level.

The tensile strengths of these five specimens of fascia varied from 1100 to 2400 gm., and averaged 1600 gm.

We believe that the values obtained on these 5 patients can be considered normal, and in this group, even a plasma ascorbic acid level as low as 0.2 mg. per 100 cc. did not cause a significant variation from the normal in vitamin C content or tensile strength of the healing fascia.

Case 4 offers a contrasting picture, which we regard as significant, because the plasma ascorbic acid was very low preoperatively (0.08 and 0.09 mg. per 100 cc. on two determinations), and because the presence of bilateral inguinal hernias offered the opportunity for contrasting experiments in the same patient. The first leg wound was allowed to heal without vitamin C therapy, other than the 100-mg. daily dose provided in the regular diet. During the ten-day healing period of the second leg wound, this dietary intake was supplemented by 100 mg. of ascorbic acid daily given by mouth. The tissue ascorbic acid level of the control biopsy of fascia taken at the time of the first operation was zero. During the ten-day healing period of this wound, the low plasma as-

corbic acid level remained unchanged, and at the end of this time the excised fascia scar still showed an ascorbic acid value of zero and a tensile strength of only 300 gm., or about one fifth of normal (1600 gm.). The control biopsy of fascia from the second leg wound also showed a zero value for ascorbic acid. This wound was allowed to heal for ten days, 1000 mg. of ascorbic acid being given orally each day in addition to the regular diet. The plasma ascorbic acid promptly rose to over 1.0 mg. per 100 cc. At the end of ten days, the healing fascia scar was excised. Its ascorbic acid content was 5.73 mg. per 100 gm., which is slightly lower than the average of 6.01 mg. per 100 gm. noted in the other cases. The tensile strength of this fascia scar was 1800 gm., a figure slightly higher than the average of 1600 gm., for the other cases, and six times as high as that (300 gm.) for the scar in the wound in the other leg, which healed without benefit of vitamin C therapy.

The results of the studies of vitamin C content and tensile strength of skin healing appear in Table 2. These figures followed essentially the

TABLE 2. *Studies on Healing of Human Skin.*

CASE NO	PRE- OPERATIVE PLASMA ASCORBIC ACID	CONTROL BIOPSY TISSUE ASCORBIC ACID	TEN-DAY TISSUE ASCOR- BIG ACID	OLD SCAR TENSILE STRENGTH
	mg /100 cc.	mg /100 gm.	mg /100 gm.	gm
1	0.63	2.49	4.04	700
2	0.20	0.99	5.82	4200
3	0.29	0.84	5.23	1500
5	0.84	0.78	5.54	600
6	1.19	1.63	4.64	1600
Average	0.63	1.35	5.05	1700
4 (first operation)	0.09	0.0	0.67	400
(second operation)	0.07	0.0	6.77	1200

same pattern as those on the healing fascial scars, although there was much more variation in the tensile-strength determinations.

If we exclude Case 4 and accept the averages of the other 5 cases as normal values, we find an ascorbic acid content of the control skin biopsy of 1.35 mg. per 100 gm., which rose to 5.05 mg. in the ten-day-old scar. The average tensile strength of these scars was 1700 gm.

Case 4 showed an ascorbic acid level of zero in the control specimen of skin, which rose only to 0.67 mg. per 100 gm. after ten days of healing without vitamin C therapy other than the 100 mg. daily in the diet. The tensile strength of this scar was 400 gm., one quarter of the normal value. The second leg wound showed no vitamin C in the control skin biopsy. After ten days of intensive vitamin C therapy, the scar had an ascorbic acid content of 6.77 mg. per 100 gm., which is

somewhat higher than the normal (5.05 mg.) Its tensile strength was 1200 gm., as against 400 gm. for the untreated scar in the same patient, and 1700 gm. for the average of the other cases.

We believe that Case 4 demonstrates conclusively two important points: that a sufficient depletion of vitamin C, reflected in a very low plasma ascorbic acid, interferes with normal wound healing, as measured by tissue ascorbic acid content and tensile strength; and that, in spite of a very low plasma ascorbic acid at the time of operation, normal wound healing can be brought about by adequate vitamin C therapy during the healing period.

There seems to be no evidence from these studies that a plasma ascorbic acid level of 0.20 mg. per 100 cc. indicates a sufficient depletion of vitamin C to interfere with normal wound healing, and this suggests that the generally accepted concept that plasma ascorbic acid levels below 0.50 mg. per 100 cc. indicate significant vitamin C depletion must be revised downward.

It was found in our work on guinea pigs that, with an adequate vitamin C intake, not only the tissues of the healing wound show a higher level of ascorbic acid than the control biopsy, but a similar though smaller rise is found in the abdominal wall at some distance from the wound. In 2 patients (Cases 5 and 6), specimens of skin were obtained at a distance from the healing wound at the time that the wound biopsy was done. As shown in Figures 8 and 9, one of these specimens showed a level of 1.88 mg. per 100 gm. in contrast to an original value of 0.78 mg. in the control biopsy, whereas the other showed a decrease from 1.63 mg. in the control biopsy to 1.10 mg. per 100 gm., in the normal skin excised ten days later.

### CONCLUSIONS

A sufficient depletion of vitamin C produces a decreased ascorbic acid content and tensile strength in healing wounds in the skin and fascia of human beings.

A fasting plasma ascorbic acid level below 0.20 mg. per 100 cc. must be reached before these changes appear.

In the presence of adequate vitamin C, the magnitude of the rise in ascorbic acid content in healing fascial scars, compared with that of control biopsies, is much greater than that shown by healing skin scars.

In spite of a low plasma ascorbic acid level at the time of operation, normal wound healing may be produced by adequate vitamin C therapy during the postoperative period.

## THE SO-CALLED "COAGULATION DEFECT" IN MENSTRUAL BLOOD\*

EUGENE L. LOZNER, MD,<sup>1</sup> ZILFEN TAYLOR, MD,<sup>2</sup> AND F. H. L. TAYLOR, PhD<sup>3</sup>  
(with the technical assistance of M. A. Adams and Harriet MacDonald)

BOSTON

THE fluidity of menstrual blood and its apparent failure to clot have been the subject of numerous investigations.<sup>1-3</sup> Although all observers agree on the existence of the phenomenon there is little agreement concerning its cause. It has been with equal enthusiasm ascribed to an anticoagulant present in uterine cervical or vaginal secretions, to the removal or absence of one or more of the factors concerned with blood coagulation and to changes in the circulating blood. The existence of this form of incoagulable blood is of interest to the investigators of blood coagulation, since it represents a phenomenon that might possibly be explained in the light of the newer knowledge of the blood coagulation reaction.

From a consideration of the theory of blood coagulation at present accepted in the United States, it appears that incoagulable blood may result from a deficiency of one or more of the plasma constituents concerned with coagulation,—calcium, prothrombin and fibrinogen,—or in a lack of the clot promoting activity associated with the euglobulin fraction of plasma, which has been found to be markedly reduced in the blood of patients with hemophilia.<sup>4</sup> Incoagulability of menstrual blood might also result from the presence of some specific anticoagulant. This communication presents the results of investigations undertaken to determine which of these various factors are concerned with fluidity of menstrual blood.

## METHODS

At the suggestion of Dr. George Van S. Smith, of the Fearing Research Laboratory, Free Hospital for Women, the collection of menstrual blood was made by the insertion of a rubber cup,<sup>5</sup> which acted as an occlusive pessary, high in the vagina. Collections were usually made for twelve hour periods, after which the contents of the cups were transferred to blood bottles, examined for the presence of clots, and placed in a refrigerator. For certain purposes, collections were made occasionally for shorter periods. Ten samples of menstrual blood were collected in this manner from 5 healthy women.

The methods for studying the effect of menstrual blood on normal human and hemophilic blood were those previously described from this laboratory. The rabbit brain thromboplastin used in the investigation was prepared by our modification of the method of Quick.<sup>6</sup> Thrombin was obtained from prothrombin, prepared by the method of Seegers et al.,<sup>6</sup> by the action of rabbit brain thromboplastin.

For control experiments against menstrual blood, two well known laboratory forms of incoagulable blood were used: citrated and defibrinated blood. In the experimental work reported below, the observations were carried out on the supernatant fluids after centrifuging, at 1500 r.p.m. for ten minutes, samples of citrated, defibrinated and menstrual blood. All observations were made in a constant temperature water bath at 37.5°C. For the sake of brevity, one typical experiment on each phase of the investigation is given. The results in all were entirely similar.

## EXPERIMENTAL RESULTS

The presence of an anticoagulant in menstrual blood was investigated by the placing of 0.1 cc

of citrated, defibrinated and menstrual bloods in glass tubes and the addition of 2 cc. of fresh uncoagulated normal venous blood to each, with a proper control. Table 1 shows conclusively that no

TABLE 1. *The Effect of Samples of Citrated, Defibrinated and Menstrual Blood on the Coagulation Time of Normal Venous Blood.*

Defibrinated blood	2
Menstrual blood	3

prolongation of the coagulation time of normal blood occurred as a result of the addition of any of the three preparations. With menstrual and defibrinated blood, there was indeed a shortening of the coagulation time of the normal blood. This indicates the presence of clot-promoting activity rather than that of an anticoagulant.

These observations were repeated, hemophilic blood being used in place of normal blood. The results are shown in Table 2. It will be observed

TABLE 2. *The Effect of Samples of Citrated, Defibrinated and Menstrual Blood on the Coagulation Time of Hemophilic Venous Blood.*

PREPARATION ADDED	COAGULATION TIME min.
None (control)	69
Citrated blood	12
Defibrinated blood	7
Menstrual blood	3

that again there was no prolongation, but a sharp diminution, of the coagulation time of the hemophilic blood. Menstrual blood has therefore an abundance of clot-promoting factor for hemophilic blood. Such an activity has been described as occurring in normal, cell-free, citrated plasma.<sup>4</sup> The data show that menstrual blood contains even more of this factor than citrated normal blood.

Since the presence of an anticoagulant could not be demonstrated in any of the samples of menstrual blood, observations were directed toward an attempt to discover whether one or more of the factors concerned in the blood-coagulation reaction were diminished or absent.

Total calcium determinations on menstrual blood were always within the normal limits obtaining for circulating venous blood. The data of Tables 1 and 2 indicate quite clearly that menstrual blood also contains sufficient clot-promoting activity to initiate blood coagulation in both normal and hemophilic blood. However, to establish beyond question that the fluidity of menstrual blood was not due to deficiency either of calcium

or of thromboplastin, 0.1-cc. amounts of a solution containing 0.25 per cent calcium chloride, with and without the addition of a 0.1-cc. solution of rabbit-brain thromboplastin, were added to 0.1-cc. samples of citrated, of defibrinated and of menstrual blood in considerable excess (Table 3). It is evident that the addition of neither calcium nor both calcium and rabbit-brain thromboplastin caused clotting of the menstrual blood. In this respect, the menstrual blood resembled defibrinated blood. Following the addition of calcium and rabbit-brain thromboplastin to citrated blood, coagulation occurred in the normal time of twenty-

TABLE 3. *The Effect of Calcium Chloride and of Calcium and Thromboplastin Solutions on Samples of Citrated, Defibrinated and Menstrual Blood.*

Menstrual	Calcium chloride and thromboplastin	No clot

five seconds. By exclusion, a deficiency or absence of prothrombin or fibrinogen, or both, appears to be the cause of the fluidity of menstrual blood. This hypothesis was investigated by efforts to demonstrate fibrinogen in the menstrual fluid and, as shown below, by the addition of prothrombin and fibrinogen to the menstrual blood. The presence of fibrinogen could not be demonstrated in menstrual blood by any of the standard chemical procedures.

Table 4 shows that the addition of 0.1 cc. of thrombin to 0.1-cc. samples of menstrual and of

TABLE 4. *The Effect of Thrombin, Fibrinogen, and Prothrombin and Fibrinogen Solutions on Samples of Citrated, Defibrinated and Menstrual Blood.*

Menstrual	Fibrinogen	No clot
Citrated	Prothrombin and fibrinogen	360
Defibrinated	Prothrombin and fibrinogen	60
Menstrual	Prothrombin and fibrinogen	71

defibrinated blood preparation caused no coagulation. This indicated conclusively the absence of fibrinogen. However, the restoration of 0.1 cc. of fibrinogen alone was unsuccessful in causing 0.1-cc. samples of menstrual blood and of defibrinated blood to clot. No effect was expected with citrated blood, since a full quota of fibrinogen was

present, as shown by clotting following the addition of thrombin. When, however, a mixture containing 0.1-cc. each of fibrinogen and prothrombin was added to 0.1-cc. samples of menstrual blood and of defibrinated blood, clotting occurred abruptly. The presence of the increased titer of clot-promoting substance in both menstrual and defibrinated blood caused the coagulation time, when excess fibrinogen and prothrombin were added, to fall below that of citrated blood.

### DISCUSSION

In their behavior toward thrombin, prothrombin and fibrinogen, the menstrual blood and the defibrinated blood, or serum, were strikingly similar. The observations indicate that the fluidity of menstrual blood is caused by the absence of both prothrombin and fibrinogen. Expressed in common language, it follows that menstrual fluid is blood that has already clotted, and that there is no "coagulation defect." Hence, menstrual blood is serum containing formed elements and epithelial debris.

A natural question arises. If menstrual blood has already clotted, where are the clots? It must be remembered that menstrual blood is slowly excreted and that much of the fibrin formed has had time to be subjected to lytic action. Only two of the samples of menstrual blood, however, showed any increased fibrinolytic power. The non-protein nitrogen of menstrual blood was also not increased. Furthermore, it is known that the presence of small clots in normal menstrual exudates is common.<sup>7-9</sup> When menstrual flow is copious or abnormally increased,—that is, when there is a faster flow,—the presence of large clots is a characteristic finding. Examination of the menstrual-blood samples used in this investigation showed macroscopic clots in 3 cases.

One clinical application of these observations lies in the interdiction, by some surgeons, of operations during the menstrual period. We have been unable to demonstrate any change in the coagulability of the circulating blood during the men-

strual period. This, together with the findings recorded, indicates that the fluidity of menstrual blood alone does not constitute a reasonable basis for postponing surgical operations to the intermenstrual period. However, patients who suffer from a true hemorrhagic diathesis during the menstrual period have been reported. In these rare cases, when the platelet count is low, operations should of course be deferred until this condition is remedied or absent.

It is interesting that Hippocrates<sup>10</sup> made studies on the menstrual blood of women three thousand years ago. He observed:

The menstrual blood is thicker, redder, and flows more copiously about the middle period of the discharge than either at its commencement or termination. Its amount in health is about twenty ounces in two or three days,—the usual period,—although great diversity exists in this respect, depending on the constitution of the individual. *The blood which is discharged, is red like that of victims, and it coagulates promptly if the woman is in health [italics ours].*

### CONCLUSIONS

From the evidence presented, it is apparent that menstrual blood is blood that has already clotted. There is therefore no true "coagulation defect," and menstrual blood is a suspension of the formed elements of blood and tissue debris in serum.

## BILE-DUCT RECONSTRUCTION WITH VITALLIUM TUBES\*

## Report of a Case

HOWARD M. CLUTE, M.D.†

BOSTON

STRICTURES of the common bile duct are almost invariably caused by an injury to the duct during some operation on the biliary tract. These surgical accidents carry in their train complications that are always serious and very frequently fatal, not only because of the accompany-

to-end sutures of the duct, transplantation of external biliary fistulas, anastomosis of the duct with the gastrointestinal tract, and replacement of the duct by a rubber tube have all been used.

Plastic repair of the duct in simple strictures and anastomosis of the common hepatic duct to

FIGURE 1.

*The strictured area high in the common hepatic duct has been exposed. ing obstruction and infection of the biliary tract, but also because of the dangers and frequent failures that accompany attempts at surgical repair.

The methods used for the surgical repair of bile-duct strictures and injuries have been slowly developed over the last quarter of a century. Plastic repair of the bile duct on the Heineke-Mikulicz principle is the simplest device available. End-

the stomach or duodenum in the more serious strictures have given the best results. Transplantation of external biliary fistulas has had but little success, and is now rarely used. Replacement of a portion of the common bile duct by a rubber tube is successful so long as the lumen of the tube remains free of bile salts. Usually, however, the bile salts produce changes in the rubber tube, and deposits in its lumen sufficient to cause obstruction of the flow of bile. I removed one rubber tube from the common duct seven years after

\*Presented at the annual meeting of the New England Surgical Society, Hanover, New Hampshire, September 6, 1941.

†Professor of surgery, Boston University School of Medicine; surgeon-in-chief, Massachusetts Memorial Hospitals.

it had been inserted. There was almost complete obstruction of its lumen by bile salts and detritus, and the rubber itself was friable and crumbly. I have also seen deposits of bile salts in the lumens of T tubes that had been in place but a few weeks. It is generally admitted, I believe, that rubber tubing does not offer a safe medium for use in repairing serious injuries to the common bile duct.

It occurred to Dr. Herm in Pearce, of Rochester, New York, that a vitallium tube might be used

viously, and hemorrhage had occurred from the cystic artery. A clamp was hurriedly applied and left in place for 24 hours. It apparently included the cystic artery and the uppermost portion of the common hepatic duct in its grasp. The common duct was explored 4 months later, because of attacks of pain, fever, chills and jaundice. No stones were found. A stricture was discovered, but was considered inoperable.

At operation on July 27, 1939, I found a stricture, almost complete, very high in the common hepatic duct. The stricture was incised longitudinally, and a rubber T tube placed in it. The patient was well for 5 months with the tube in place. It was then accidentally pulled out. Soon after that, attacks of pain, chills, fever and jaundice recurred.

At operation on April 14, 1940, I exposed the strictured common duct with great difficulty. About 0.3 cm. of the common hepatic duct was present. The duodenum was freed, and a hepaticoduodenostomy was performed. A ring of fibrous tissue about the opening of the common hepatic duct made me fear that the new opening might contract and obstruct. After 6 or 7 months, this occurred, and the attacks of pain, chills, fever and jaundice returned.

On November 29, I again exposed the common duct area, cutting the duodenum free from its anastomosis to the

to replace or reconstruct an injured common bile duct. He<sup>1</sup> showed that bile made no changes in vitallium, and he has successfully implanted vitallium tubes in 2 cases of common duct stricture. Through the kindness of Dr. Pearce, I was given an opportunity to employ this method in a very difficult common duct stricture. Vitallium tubes of the required type, which differ in shape from the ones used by Dr. Pearce, were obtained\*. The case is reported so that other surgeons may be familiar with the possibilities of vitallium tubes in bile duct strictures.

#### CASE REPORT

Mrs. M. L. (2488), a 38 year old woman, was admitted to the hospital on June 30, 1938. Cholecystectomy for gallstones had been performed elsewhere 16 months pre-

FIGURE 3

*The vitallium tube has been placed in the common duct. It should be noted that a portion of the duct is completely lacking. Continent fat tabs and omentum were used to cover the exposed tube.*

common hepatic duct. The anastomosis had diminished to pin point size. By means of an opening in the duodenum, a probe was inserted through the ampulla of Vater, and demonstrated the distal portion of the common duct. The duodenum was closed, and the common hepatic duct was dissected free as it lay in liver tissue (Fig. 1). Its opening was a ring of firm, fibrous scar tissue. In the hepatic ducts was much detritus, as well as many tiny

\* Manufactured by the Austral Laboratory, Incorporated, New York City.

black gallstones. The opening of this duct was enlarged so that the trumpet-shaped end of a vitallium tube could be inserted and held securely with silk sutures (Fig. 2). The distal end of the tube was placed in the distal portion of the common bile duct, about 2 cm. of which was absent. Omentum was brought in to surround the tube (Fig. 3). A jejunostomy was made for postoperative feeding. A

examination at this time showed no evident change in the position of the tube (Fig. 4). No further attacks have occurred, and the patient appeared to be very well when last seen (March, 1942).

The technical difficulties in this case were only those of exposing both the common hepatic duct

FIGURE 4.

*This x-ray film, taken some months postoperatively, shows the vitallium tube in the common bile duct and its relation to the barium-filled stomach.*

drain was placed in the region of the anastomosis, but not close to it.

Recovery was entirely uneventful, the highest temperature being 99.4°F. 2 days after operation. The patient was entirely well for 6 months and then had one attack of pain and transient jaundice. This was followed by a small wound infection that quickly cleared up. X-ray

above and the common bile duct below, in a field in which the landmarks had been largely concealed by inflammatory tissue and adhesions following the previous operations. Placing the tube in the bile duct was not difficult, because the diameter chanced to be just right; furthermore,

the ring of fibrous tissue in the common hepatic duct held the trumpetlike proximal end of the tube firmly in place. It is noteworthy that the

tion of a vitallium tube in the duct. I do believe, however, that such a tube can remain indefinitely in the body without being affected by the body

vitallium tube bridged a gap of about 2 cm in the bile duct.

Dr. Benjamin W. Seaman,<sup>2</sup> of Hempstead, New York, reports that his assistant, Dr. Carl Hettesheimer, has transplanted a vitallium tube into a strictured bile duct with success. An absence of about 2 cm of the common duct was replaced. The patient was well nearly four months after operation.

It is apparent that in the future one must have various sizes and shapes of vitallium tubes at hand for the different sized common ducts that may be encountered, although some alteration of the shape of the tubes can be made by cutting them with heavy scissors. In fact, it is now possible to obtain various shapes and sizes of tubes (Fig. 5).

I do not recommend that every case of stricture of the common bile duct be treated by implant-

fluids, and that increasing usefulness of such tubes will be evident. I am satisfied that, in the case reported, such a tube was of the greatest help to the surgeon, and a lifesaving device for the patient.

Meigs and Langdon Parsons, which appeared in the February 26 issue of the *Journal*, the words "first" and "second" on page 324, column 2, lines 26 and 27, should be transposed.

## MEDICAL PROGRESS

### TRICHINOSIS AND ENTEROBIASIS: THEIR IMPORTANCE IN NEW ENGLAND\*

DONALD L. AUGUSTINE, Sc.D.†

BOSTON

FROM a review of the literature, it is evident that trichinosis still remains the most frequent and the most serious of the parasitic infections in New England. It is also clear that enterobiasis, or pinworm infection, is probably second in frequency. Although the latter is definitely less serious than trichinosis, its incidence is such as to be of notable concern among pediatricians and public-health workers.

#### TRICHINOSIS

The extraordinary frequency of trichinosis in the United States began to be appreciated when Queen,<sup>1</sup> in 1931, briefly reported that examinations of diaphragms from 344 consecutive cases at autopsy in Rochester, New York, showed 59 (17.5 per cent) infected with trichinae, and that in a similar study made on 58 cases at autopsy in Boston, 16 (28 per cent) proved to be trichinous. Queen's data were in sharp contrast to earlier estimations, which placed the incidence of infection from 0.5 to 2.0 per cent for most civilized countries. Some inadequate data, however, did indicate a much higher rate of infection for some parts of the United States. These early figures were based on direct microscopic examination of relatively small bits of muscle, whereas Queen utilized artificial digestion of 50-gm. portions of the diaphragm in his cases.

Shortly after the announcement of Queen's findings, similar surveys were undertaken in nearly every section of the country. The results of these local studies have shown an astonishingly high incidence of trichinosis throughout the whole United States, ranging from 3.5 per cent in New Orleans<sup>2</sup> to 36.0 per cent in Cleveland.<sup>3</sup> These recent data do not indicate, as they at first suggested, that trichinosis has been rapidly increasing in this country or in any section of this country. On the contrary, the situation is probably improved in many localities over that of fifty years ago. It should be recalled, however, that within recent years two major epidemics of trich-

inosis have occurred within the New England states, namely, the Portland epidemic of 1935, which involved 71 persons, with 2 deaths,<sup>4</sup> and the epidemic among members of the Civilian Conservation Corps at Camp Charles M. Smith, Waterbury, Vermont, three years later, in which there were 64 cases but no deaths.<sup>5</sup>

Human trichinosis almost invariably has its source in pork infected with encapsulated larvae of the parasite. As an exception, attention repeatedly has been called to California outbreaks of the disease, which originated from eating jerked bear meat. Recently, a number of cases have been reported from Germany, following the eating of game and fur-bearing animals; in several cases, the infection originated from nutrias.<sup>6</sup>

Trichinosis in swine is usually the direct result of their eating raw trichinous pork, either in garbage or in offal at the time of slaughter. The primary source of rat trichinosis is, like that for swine, raw; infected pork scraps in garbage collected for swine, or in scraps picked up in the market districts or at abattoirs. Because of the high frequency of trichinosis in rats, it has long been held that rats are important reservoirs of infection for the disease in swine. Although swine may eat dead rats thrown to them, they are seldom known to kill and eat rats, even when they are numerous in hog pens. For the most part, rats and pigs seem to get along on quite friendly terms.<sup>7-9</sup>

The infection in rats may be considerably spread through cannibalism, but such infection probably is rarely transmitted to swine. Thus, human, porcine and rat trichinosis are all chiefly of porcine origin.

Since the young trichinae, the progeny of the adult male and female worms in the intestine, are passively carried to all parts of the body by the lymph and blood streams, the question early arose concerning the possibility of prenatal infection, as in ascariasis, hookworm infection and several other parasitic worm infections in which a blood-stream invasion is characteristic in the developmental cycle. Hood and Olson,<sup>10</sup> in 1939, found trichinae in four diaphragms from 48 infants under one year of age, and suggested that prenatal trichinosis might be a common occurrence. The weight

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

†Associate professor of comparative pathology and tropical medicine, Harvard Medical School and Harvard School of Public Health.

of careful experimental evidence, however, fails to confirm this conjecture.<sup>11-15</sup>

The cause for the failure of *Trichinella spiralis* to produce prenatal infection is not known. However, the migrating larva is strikingly less active as a tissue borer than the larvae of helminths that are known to produce prenatal infection. It is deposited directly into the lymph stream by the gravid female worm in the intestinal wall. Subsequently, it is passively carried by the blood through the lung capillaries into the arterial circulation. Its main active migration occurs when it passes from the blood vessels and penetrates a muscle fiber. If this larva fails to penetrate a striated, skeletal muscle fiber, it is quickly surrounded by a focus of acute inflammatory exudate and is destroyed. This is known to be the fate of larvae that emigrate from the vessels situated in the heart, pancreas and brain; and although no trichinae have been found in placental tissues, there is every reason to believe that some are carried to the placenta, where they are probably as effectively destroyed as in other sites not favorable for encapsulation. It appears, therefore, that the sluggish nature of the larva, together with the acute and effective response of the host against larvae that fail to become encapsulated within the striated muscle fibers, may account for the freedom of the fetus from this parasite.

Recent studies continue to stress the irregularity of the clinical course of trichinosis, and to emphasize clinical aids in the diagnosis of sporadic cases. Kaufman,<sup>16</sup> from a critical study of 12 misdiagnosed cases of trichinosis, reported one clue, which, if heeded, would have suggested the correct diagnosis, namely, a history of puffy eyelids in the patient or in a member of the immediate family, or an edema of the eyelids at the time of physical examination. He suggests that in taking a history in all acute illnesses, one make specific inquiry concerning the presence of puffy eyelids, and that if there is such a history, or if they are observed at examination, the diagnosis be seriously considered. Andes, Green and Breazeale<sup>17</sup> and Lee<sup>18</sup> similarly note that edema about the eyes is one of the commonest symptoms, even in mild infections. McNaught<sup>19</sup> has recorded a new symptom in cases of active trichinosis: so-called "splinter hemorrhages," which occur beneath and along the distal ends of the fingernail and toenail beds and form a crescentic band of ecchymosis. This manifestation appears not to have been recorded heretofore, but according to McNaught it may be expected in 60 to 70 per cent of the cases of clinical trichinosis. It furnished strong supportive evidence in diagnosis during the recent epidemics in Wolverhampton, England.<sup>19</sup> These subungual hemorrhages occur

at the time of invasion of the tissues by migrating larvae, and are of the nature of petechiae.

The presence of a blood eosinophilia, particularly a rapidly ascending eosinophilia, is generally held to be the most reliable sign of trichinosis.<sup>16-20</sup> The lack of an eosinophilia does not rule out the diagnosis, since this sign may be absent in severe fatal cases or in trichinosis complicated by a concurrent bacterial infection.<sup>20, 21</sup>

Laboratory procedures for demonstrating the presence of the parasite during the life of the patient have not been improved materially. Although migrating trichinae have been found in the blood and spinal fluid, young and encapsulated larvae in excised bits of skeletal muscle and adult worms and larvae in evacuated stools after drastic purgation, direct evidence of the parasite is usually not readily obtained.

Dammin<sup>22</sup> reports the ready finding of larvae in arterial blood from a case of trichinosis after unsuccessful examination of venous and capillary blood. He suggests the examination of arterial blood instead of venous blood.

For post-mortem examination, the compressor method and the combined digestion-Baermann method described by Nolan and Bozicevich<sup>23</sup> have been widely and successfully used. The first procedure consists in the compression of a 1-gm. sample of muscle, cut into small pieces between plate-glass slides, and examination with a low power of a dissecting microscope. The digestion-Baermann method utilizes the digestion of ground, striated muscle in artificial gastric juice; the diluted digestate is placed in a Baermann apparatus (used in hookworm studies for isolating infective hookworm larvae from soil samples), which is essentially a large funnel with a sieve that screens out the coarser particles and permits the trichinae to settle in the neck of the funnel. The compressor method has been particularly useful in detecting long-standing infections in which the trichinae are dead and calcified and would be missed with the digestion-Baermann method. The digestion-Baermann method has been used in the majority of the recent incidence studies.

Serologic and skin tests have been widely used for more than ten years. The results of observers who have had the most experience with these tests indicate that they are specific and of definite value as diagnostic aids.<sup>5, 20, 21-28</sup> In the experience of McNaught, Beard and Meyers,<sup>28</sup> the skin and precipitin tests have shown as high a degree of sensitivity as is found in any other clinical or laboratory procedure. However, limitations of these reactions for accurate diagnosis should be kept in mind. In view of the high percentage of people harboring the parasite, it is to be expected that some patients will give positive

reactions even though their illness may not be related to acute trichinosis. It was shown<sup>29</sup> and has recently been confirmed<sup>30</sup> that tissue and serum sensitivity to trichinella antigen may be present for years after a person has recovered from an attack of trichinosis. Thus, negative tests are more reliable in ruling out trichinosis than positive tests are in establishing the diagnosis.

Two types of skin reactions may develop in trichinous cases: delayed and immediate. The delayed reaction occurs during the first week of illness, and is similar to the delayed tuberculin reaction. After a second week, the skin reaction is immediate, consists of a blanched wheal surrounded by a zone of erythema, and gradually disappears about one hour after the antigen has been injected. The precipitin test does not become positive until about the fourth week of illness. It is especially useful if at first negative and later positive. For years, a chief objection to these tests was the difficulty in preparing or obtaining the antigen. At present, however, it can be obtained from at least two of the leading firms in this country that supply other biologic preparations.

A question of particular interest and one that is frequently raised in civil-court cases, is whether the patient suffers permanent injuries following recovery from acute trichinosis. Theiler, Augustine and Spink<sup>29</sup> elicited no residual symptoms from 7 patients seen from four to seven years after recovery. Warren, Drake and Hawkes<sup>30</sup> make no mention of any residual symptom in 45 patients examined three years after recovery from acute trichinosis.

The electrocardiographic findings of Spink<sup>31</sup> on 18 patients with trichinosis showed that myocardial damage, in recovered cases, is temporary. One of these patients, who showed marked signs of a weakened myocardium on the seventeenth day of illness, had a normal electrocardiogram thirty-two days later, the forty-ninth day after onset. Seven months later, the patient, on examination, complained of weakness, pain in the muscles of the extremities, dyspnea and palpitation on exertion, and slight edema of the ankles. The heart rate was regular, no murmurs were heard, and the blood pressure was 106 systolic, 70 diastolic. An electrocardiogram was normal. Beecher and Amidon<sup>32</sup> similarly reported only temporary cardiac damage in 44 cases of trichinosis followed by clinical and electrocardiographic examination.

Experimental evidence clearly supports these clinical deductions on myocardial injury in trichinosis. Graham,<sup>33</sup> in 1897, showed that myocarditis in trichinous rats is the direct result of the presence of young trichinae in the myocardium, although the muscle fiber is not penetrated. In

Graham's experiments, the greatest number of larvae occurred in the heart muscle on the ninth day of infection, and very few larvae, if any, were definitely recognized after the fourteenth day. It therefore appeared that the developing trichinae either had been killed in situ or had left the myocardium by passing back into the circulation. Zoller<sup>34</sup> confirmed Graham's findings and expressed the belief that the injury to the heart muscle was only temporary. Dunlap and Weller,<sup>35</sup> studying the disease in white rats, found myocardial damage during the period of active dissemination of the trichinae, beginning as early as five days after infection, but it was not observed as soon as active migration of the larvae had ceased. No notable alteration of myocardiac tissue was found.

Most and Abeles<sup>36</sup> have contributed a comprehensive review of the literature relating to clinical manifestations and neuropathologic changes in trichinosis of the nervous system; they report 2 of their cases, 1 of which was fatal. The patient who on admission presented signs of mild, acute encephalitis made an uneventful recovery. Thirty-one days after admission, the neurologic and mental status of this patient was normal. From the review of the literature by Most and Abeles, it appears that no extensive damage to the nervous system is to be expected in trichinosis. Berco-vitz<sup>37</sup> searched for residual symptoms of trichinosis in 70 patients recovered from one month to two years prior to his examination. He reported that of these patients, some of whom had suffered severely from the disease, 52, or 74 per cent, suffered no residual symptoms between one month and one year after recovery. Muscle weakness and muscle soreness were the chief complaints of the patients with symptoms, and these lasted for varying periods, but not longer than one year. In no case was there anything resembling a permanent disability.

From the information available, it appears evident that, at the most, vague muscle pains and ready fatigue may be expected to persist for some months after apparent recovery from trichinosis, but the repair of damage to the heart or other tissues in which the parasite does not successfully develop during the acute stage of illness is complete, and probably never results in a permanent disability.

In addition to the vast amount of study on the serologic reactions in trichinosis, there has been, during recent years, an ever-increasing interest in its immunity relations.

Without question, no other parasitic worm has so broad a host range as *T. spiralis*. Although the principal hosts, or the hosts most frequently

parasitized under natural conditions, are rats, swine and man, in all probability, any mammal can serve as a favorable host. In addition to these hosts, natural infections are now recorded in mice, domestic cats, palm civets, dogs, wolves, coyotes, foxes, pole cats, martins, ferrets, nutrias, European and American badgers, raccoons, polar bears, common bears and mongooses. Experimentally infected animals include guinea pigs, rabbits, hamsters, monkeys, sheep, cattle, gophers, horses, chickens, pigeons, magpies and rooks. Only young chickens are susceptible to muscular infection, which is of short duration.<sup>38</sup> Normal adult birds appear highly refractory to trichinosis, but muscle infection has been established in adult pigeons affected by avitaminosis.<sup>39</sup> Cold-blooded animals, fish and frogs appear to possess an absolute natural immunity against the parasite.<sup>40, 41</sup>

Recent investigations show that the diet of the host may significantly influence natural resistance to trichinosis. For example, McCoy<sup>42</sup> observed that young rats kept on a diet deficient in vitamin A are markedly more susceptible to the disease than those maintained on an adequate diet. The lowered resistance in the deficient rats was manifested by a persistence of the adult worms in the intestine, and also by the failure of these rats to develop any immunity against reinfection. Again, a diet lacking in vitamin E appears to enhance slightly the resistance of rats.<sup>43</sup>

It has been shown that animals that have recovered from an initial infection with *T. spiralis* resist reinfection.<sup>44-46</sup> When heavy doses of trichinae are fed to rats recovered from three or more sublethal infections, most of the trichinae are expelled after a few hours from the intestine.<sup>47</sup> Severe diarrhea is characteristic in reinfection in animals. It appears that the intestinal tract of the immune animal is "sensitized" following previous infection, and that the worms are thereby rapidly expelled on reinfection.<sup>20</sup> Whether recovery from an initial infection confers similar immunity in man is not known. It seems possible, however, that when the disease in man is marked by acute gastrointestinal symptoms and is not followed by other symptoms, the patient may have recovered from a previous infection.

Mauss<sup>15</sup> reported that the offspring of trichinosis rats, rabbits and hamsters are less susceptible to trichinosis than the offspring of uninfected mothers. This lowered susceptibility is of short duration, being lost within about three weeks of birth. The transmission presumably occurs through the mother's milk.

Artificial immunity to *T. spiralis* has been produced by intraperitoneal injection of living larvae, of heat-killed larvae or of dried and powdered

larvae.<sup>48</sup> The resistance induced by these methods is not so great as that brought about by active infection.

Conflicting results have been obtained from experiments on passive transfer of acquired immunity to trichinosis. Claims of beneficial results in acute cases of the disease in human beings by the use of serum from patients recovered from the infection<sup>49</sup> are not generally supported by animal experimentation. Culbertson and Kaplan<sup>50</sup> recorded passive immunization of mice by the injection of immune rabbit serum. The degree of resistance induced was very low. McCoy<sup>48</sup> obtained no evidence that immunity to trichinosis can be transferred passively by the use of serum from superinfected animals.

New light on the mechanism of immunity to trichinosis has been presented by Oliver-González.<sup>51</sup> According to him, two types of antibody appear in the serum of rats as a result of infection with *T. spiralis*—one acts specifically on the adult worms, and the other on the larvae. The former appears in the serum about the fifteenth day after infection, disappears by the fiftieth day and reaches its highest titer during repeated superinfection. By passive transfer, it partially protects rats against the intestinal stage of infection. In vitro, it causes precipitation at the mouth, anus and vulva of the female worms, and this is sometimes followed by death of the adult worms. The antilarval substance, which does not appear in the serum until about the thirtieth day after infection, reaches its highest titer about the fiftieth day after infection, but is not increased during repeated superinfections. In vitro, it causes oral, but no anal, precipitation, and sometimes death of the larvae. It gives little or no protection to rats against the intestinal stage of trichinosis.

From the results of Oliver-González's<sup>51</sup> studies, it is apparent that the varying results of earlier workers on passive transfer of acquired immunity to trichinosis may be attributed to the use of serums taken too long after infection, that is, at a time when the antibody content of the serum is low or absent and, particularly, in experimental studies, to the use of rats and guinea pigs, which, according to Oliver-González, do not produce such potent antibodies as rabbits do.

Experimental studies have failed to reveal a specific drug either for the removal of adult worms from the intestine or for the destruction of larvae in the blood stream and muscles. Results from the use of calcium lactate, parathormone, irradiated ergosterol and related substances forcing calcification of encapsulated trichinae in experimental animals do not warrant their use in the treatment of human infection.<sup>52</sup>

Although much has been written and said, little has been accomplished within recent years in the prevention and control of trichinosis. Until drastic changes are made in the methods of garbage disposal throughout the country, the only effective means of control must remain with the housekeeper, which means that all pork must be cooked thoroughly before it is eaten.

#### ENTEROBIASIS

*Enterobius vermicularis*, the pinworm, is a parasite of human beings only. It occurs, in its various stages of development, from the lower ileum through the rectum. Unlike those of other intestinal worms, the eggs of the pinworm are not deposited in the intestinal tract. The gravid female worm characteristically migrates down the large intestine and through the rectum, especially at night, and lays her eggs on the perianal skin of the patient. The worms may travel a distance of several centimeters from the anus within an hour after the patient has retired.<sup>53</sup> Locomotion, however, ceases soon after exposure to the air. The eggs are then discharged by violent uterine contractions, and masses of eggs appear at the region of the vulva of the worm. The spent female worm then becomes shriveled and may drop from the body into the bed clothing.

Owing to this peculiar behavior of the female worm during oviposition, the usual methods of examination of feces for parasites are wholly inadequate and unreliable for detecting pinworm eggs. Thus far, the most reliable means of diagnosis has been the finding of the eggs collected in scrapings from the perianal skin. Several techniques have been recommended for obtaining the eggs, such as the use of spoons, glass tubes and rods, spatulas and cotton pledgets, of which the first practical and efficient procedure was devised by Hall in 1937.<sup>54</sup> By Hall's method, the tip of a glass rod is covered with a square of cellophane held in place on the rod by a rubber band. The opposite end is carried through a rubber cork fitted into a glass tube, which prevents drying and loss of material during transportation and ensures safety of the carrier from infection. The swab has been generally referred to in the literature as the N. I. H. (National Institute of Health) swab.

To obtain a specimen for examination, the cellophaned end of the swab is passed radially among the perianal folds and over the neighboring perineum. Subsequently, the piece of cellophane, with the scrapings adhering to it, is removed from the glass rod and placed, face down, over two drops of physiologic saline solution, and examined under the microscope. In addition to the eggs

of the parasite, vestiges of female worms or whole female worms may be present in the scrapings. Swabs should be taken during the night or in the morning before the patient bathes or defecates, preferably on at least seven days if the first results are negative.

Since the introduction of the N. I. H. swab, new studies on the incidence and epidemiology of enterobiasis have appeared in rapid succession. Cram<sup>55</sup> has summarized the results of various investigators on the incidence of pinworm infection, as revealed by the use of the N. I. H. swab, in the United States, Puerto Rico, Canada and the Philippines. Of a total of 22,376 persons examined, 9703, or 43 per cent, were positive. The distribution of positive cases is not spotted, as might be expected. The infection appears to be astoundingly high in the Boston area. Weller and Sorenson,<sup>56</sup> in 1941, in a clinical study of 505 white children, between the ages of two and twelve years, living in the Boston area, found 97, or 19.2 per cent, infected. In this group, 415 children were examined with one swab only. Of these, 74 cases, or 17.7 per cent, were positive. The remaining 90 cases were examined with two swabs. Of these, 23 cases, or 25.5 per cent, were positive. These later data illustrate the value of repeated swabs in diagnosis. It is probable that the findings of Weller and Sorenson may reflect quite well the frequency of pinworm infections in children throughout New England.

Recent studies have emphasized the familial nature of pinworm infection. Multiple cases are the rule rather than the exception, and frequently all the children of the family are infected, as well as one or both of the parents. Although families with pinworm infections are found most frequently in older, congested, residential sections, pinworm infections are not confined to any section or to any socioeconomic level.

Clinical symptoms in pinworm infection are exceedingly variable in both their nature and degree, being apparently absent in some cases and severe in others. The greater proportion of the cases studied by Weller and Sorenson<sup>56</sup> were essentially asymptomatic, although anal pruritus, skin lesions, enuresis, loss of appetite and masturbation were commoner in the children with pinworms than in those who did not have pinworms. Brady and Wright<sup>57</sup> noted gains in weight, improvement in color, disappearance of dark circles under the eyes, improved appetite and, particularly, improved social attitude and scholastic standing in many infected children after successful treatment. These authors did not find that enuresis, frequently attributed to pinworm infection, occurred with any greater frequency in their

infected than in their noninfected group. It appears, however, that pinworm vaginitis occurs much more frequently than has been generally considered in the past. Of 45 cases in young girls examined by Brady and Wright, 14, or 31 per cent, were positive on one vulvar swab made at the introitus. Ten girls showed a mucoid vaginal discharge believed to be due to irritation of the genital tract from parasites migrating between the labia and into the vagina.

Africa<sup>58</sup> has summarized the literature on reported cases of enterobiasis in which pinworms migrated through the vagina and uterus into the fallopian tubes, causing symptoms of salpingitis, or into the peritoneal cavity, where they were found encapsulated in the peritoneum. He points to the fact that all such cases were observed accidentally during operation or at autopsy, which indicates that the condition may not be unusual, and that, obviously, many cases must have escaped notice.

The role of the pinworm in appendicitis is still an unsolved problem. Botsford, Hudson and Chamberlain<sup>59</sup> have expressed the opinion that the parasite may give rise to the syndrome of appendicitis without characteristic histologic changes. According to Chandler et al.,<sup>60</sup> it is only the fourth-stage larva of *E. vermicularis* that habitually burrows into mucous membranes, especially of the appendix, and there is a definite period six to nine days after infection when symptoms of invasion appear, followed four to seven days later by migrating worms from the anus. It appears, therefore, that the transient nature of the pinworm in the wall of the appendix may explain the many failures in demonstrating the worm at operation; because of these failures, the conception has become current that the parasite is not an important factor in appendicitis.

Wright, Brady and Bozicevich,<sup>61</sup> in 1938, recommended gentian violet for the treatment of enterobiasis; they obtained a cure rate of over 90 per cent, as indicated by the N. I. H. swab technic. The results of further tests on the specificity of the gentian violet for pinworms by D'Antoni and Sawitz,<sup>62</sup> Miller and his associates<sup>63</sup> and Wright and Brady<sup>64</sup> uphold the early results of Wright, Brady and Bozicevich. For adults, the recommended dose is 0.065 gm. (1 gr.) of the drug in a water-soluble, coated, four-hour type tablet given three times daily before meals for a period of eight days, followed by a seven-day rest period, after which treatment is repeated for eight additional days. For children, the recommended daily dosage is 0.01 gm. (1/4 gr.) for each year of apparent age. According to the authors cited above, the

drug, in general, is well tolerated. Contraindications include concomitant Ascaris infection, any disease of the gastrointestinal tract, cardiac, hepatic or renal disease and pregnancy.

The control of pinworm infection is exceedingly difficult. The pinworm differs in its development from all other nematodes infecting man. The egg requires no prolonged period of incubation before it reaches the infective stage. When laid, the egg already contains an embryo, which becomes fully developed and infective on the skin of the patient within six hours. Infection is direct, that is, it follows ingestion of this egg.

During the last few years, particular attention has been given by investigators to the mechanism of pinworm infection. The infected patient may readily contaminate the hands while scratching the perianal regions to relieve itching caused by migrating worms, or when using the toilet. Pinworm eggs have been removed so frequently from under the fingernail that the examination of such scrapings has been advocated as a means of establishing the diagnosis. Sooner or later, the eggs on the hand are carried to the mouth of infected persons (autoinfection), or they may contaminate objects that can carry the infection to other persons. There is definite evidence that pinworm eggs may be carried about by air currents. Lentze<sup>65</sup> demonstrated experimentally that viable pinworm eggs could remain suspended in air for two minutes, and, on conclusion of the experiment, recovered eggs from his own nasal passages. Particularly important, at this time, are the epidemiologic studies on pinworm infection by Nolan and Reardon,<sup>66</sup> D'Antoni and Sawitz<sup>62</sup> and Sawitz, D'Antoni, Rhude and Lob.<sup>67</sup> Nolan and Reardon studied the distribution of pinworm eggs in household dust from seven homes, in each of which at least one member of the family was heavily infected. Viable eggs were found in dust taken from the floor and furniture and from the top molding of doorways and ceiling lights. Although the contamination of the furniture might have come directly from infected persons, the finding of viable eggs at the higher levels definitely points to air transportation. D'Antoni et al. obtained similar results from their study at six institutional homes for children. Viable eggs were found in all samples of dust collected in the dormitories from floor cracks, ledges of pillars of doors, windows and toilet partitions, at heights under eight feet from the floor. From these studies, it appears that the obstinate infection, which may persist for months or even years in spite of repeated anthelmintic treatment, is more probably the result of constant reinfection, frequently air borne,

than of an internal multiplication and development of the worms, as generally held in the past, but lacking confirmation.

Pinworm eggs are markedly resistant to physical and chemical agents. A temperature of 55°C. and above kills the eggs in a few seconds. At body temperature and on a damp base,—as on the human skin, especially under the fingernails,—they may survive for about ten days.<sup>65</sup>

Jones and Jacobs,<sup>68</sup> in a critical study on the survival of pinworm eggs under known conditions of temperature and humidity, found temperatures above 28°C., with humidities below 50 per cent, definitely destructive within twenty-four hours. None of the eggs survived after sixteen hours at a temperature of 36°C. and a relative humidity of 38 to 41 per cent. In water, at 3 to 5°C., the eggs survived for eighteen days. Ordinary disinfectants in strengths commonly used in the home do not kill pinworm eggs.

The futility of attempting to control pinworm infections in a household by hygienic measures alone was demonstrated in 1940 by D'Antoni et al.<sup>62, 67</sup> A vigorous cleanliness program was put into force for six weeks in a children's home that had been kept scrupulously clean. At the beginning of the experiment, extra housemaids cleaned every room with hot water and soap daily, and at night the children wore short cotton pants, which were changed and sterilized daily. Bed sheets were changed and sterilized daily, and underwear was changed daily and sent to the laundry. Nail brushes were provided for each child, and their use was enforced. Two showers were taken daily, instead of one. At the close of the experiment, swab examinations showed an increase from 38 to 51 per cent in the incidence of pinworms. In a similar home, treatment included prolonged use of gentian violet without special hygienic measures. Post-treatment swabs showed that a cure of approximately 90 per cent had been obtained.

Thus, hygienic measures alone appear to be of little value in the eradication of pinworm infection in the household, and control lies in simultaneous medical treatment administered to all infected persons within the household for a time sufficiently long to cover the period of survival of eggs in the surroundings.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28121

#### PRESENTATION OF CASE

*First admission.* A forty-four-year-old chauffeur was admitted to the hospital because of epigastric discomfort, chills and jaundice of about three days' duration, following a long story of related complaints.

Twenty-six years before entry, the patient was confined to bed for six months by an illness characterized by abdominal pain, jaundice, edema and passage of bloody stools. He had a temperature of 105°F. for one month, and subsequently lost his hair and desquamated extensively. Following recovery, he was well for a long time. Ten years before entry, he experienced an attack of "gas in the stomach," accompanied by jaundice, lasting two days. Seven years before entry, following breakfast, he developed a sharp midepigastriac pain, which responded well to morphine given by a physician. Jaundice and fever followed, and the patient was therefore taken to a hospital, where roentgenograms were said to show an inflamed, stoneless gall bladder. While in that hospital, he suddenly "vomited bile," and was immediately relieved of his pain. After this episode, he had occasional spells of upper abdominal discomfort, sometimes followed by a yellowing of the scleras. He avoided fatty foods, on the advice of a physician. Four days before entry, he returned home from a trip in the country, feeling very tired. He noted slight epigastric discomfort, but this went away the next morning. This abnormal sensation, described as a "gripping, uncomfortable feeling, not exactly a pain," reappeared in the afternoon. It did not radiate or extend from the midepigastrium. Again, it was relieved when the patient lay down to rest. That night, a mild chill occurred, followed by sweating. On the morning of the second day before entry, the gripping sensation returned. The patient felt ill, and fasted. His physician found that he had a temperature of 101°F., that the scleras were jaundiced, and that the urine was "very dark orange." On the day preceding entry, the skin felt itchy, the jaundice was deeper, and the stools were clay colored.

On admission, the patient was mildly jaundiced. His general condition seemed good. There was slight tenderness in the epigastrium (positive

Murphy's sign). The liver edge was just palpable. Examination of the heart and lungs was negative.

The temperature, pulse and respirations were normal. The blood pressure was 138 systolic, 98 diastolic.

Examination of the blood showed a white-cell count of 8700 with 75 per cent polymorphonuclears, and a red-cell count of 4,440,000 with 95 per cent hemoglobin. The hematocrit was 53.4 per cent. The blood sugar was 77 mg. per 100 cc., the chloride was 97.2 millicequiv. per liter, and the nonprotein nitrogen was 36 mg. per 100 cc. The van den Bergh reaction was biphasic, with a serum bilirubin of 9.2 mg. per 100 cc. The prothrombin time was normal.

The urine was normal, except for a + test for bile pigment. The stools were light brown, with a trace of bile pigment.

A roentgenogram of the gall bladder showed this organ to fill faintly with dye. There was no definite contraction after a fatty meal. The Graham test was considered positive.

On the fourth hospital day, duodenal drainage gave clear, dark green "A" and "C" specimens. No "B" bile could be obtained. After prolonged drainage, milky white bile was obtained from an uncertain locality. Crystals resembling calcium bilirubinate were found on microscopic examination of the bile obtained after the administration of magnesium sulfate.

The temperature continued to be normal. On the seventh hospital day, a laparotomy was performed. The liver appeared "diffusely scarred," suggesting "early cirrhosis." A large gall bladder, covered by tenuous omental adhesions, was removed. The common duct, dilated to a diameter of more than 2.5 cm., was opened, and freed of two pigment stones. The ampulla was subjected to dilatation and irrigation. A T tube was sutured into the common duct, and closure was effected, with drainage to subhepatic region. The pathological report was chronic cholecystitis and choledocholithiasis.

Postoperatively, there was elevation of temperature to 100°F., recurring for several days. Although considerable amounts of clear bile drained from the tube left in the common duct, the patient continued to be jaundiced. One week after operation, the serum bilirubin was 10.4 mg. per 100 cc., with a biphasic van den Bergh reaction. The blood chemical findings were otherwise essentially negative.

On the sixth postoperative day, roentgenograms showed that a Hippuran injection through the T tube filled the biliary tract well. The tract appeared distended. Two days later, a similar injection showed marked dilatation of the common duct, with two filling defects, suggesting stones,

at the lower end of this duct. There was extensive retrograde filling of the hepatic duct and of two irregular cavities in the liver suggesting abscesses.

By the twenty-fourth postoperative day, the serum bilirubin fell to 4.2 mg. per 100 cc., and there was only slight residual jaundice. The patient was discharged with the T tube still in place, draining an average of 300 cc. of bile a day.

*Final admission* (one month later). The patient had been followed in the Out Patient Department, and continued on "bile cocktails" and bile salts by mouth. Constant drainage from the tube was clear except on one occasion when there was a small amount of yellow granular sediment. After two weeks, drainage ceased, and the jaundice cleared entirely. Two weeks later, the tube came out of place during an examination with Hippuran, which showed the biliary tract still dilated, with no evidence of stones.

The patient was readmitted to the hospital because of sudden onset of vomiting and acute abdominal discomfort about four hours previously. After an hour and a half, the discomfort progressed to severe pain. During the next half hour, the patient had a severe chill. He vomited twice again, and was brought to the hospital.

On readmission, he again showed very slight jaundice. The scar of the laparotomy and drainage was well healed. The entire abdomen was distended, with tenderness and muscle spasm that were most marked in the right upper quadrant. Signs of peristalsis were absent. The heart and lungs were normal.

The temperature was 102°F., the pulse 130, and the respirations 18. The blood pressure was 140 systolic, 90 diastolic.

Examination of the blood showed a white-cell count of 13,600 with 88 per cent polymorphonuclears and 4 per cent band forms, and a red-cell count of 5,680,000 with 105 per cent hemoglobin. The urine showed a + test for albumin, and a ++ test for bile pigment. The stools were positive for bile pigment and for occult blood. A Miller-Abbott tube was passed as far as the pylorus, but could not be manipulated past this point. Clyses of glucose were given. The patient's temperature fell to normal, rising to 101°F. on the third hospital day. On the fourth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: This is a long and complicated story. Is there anyone to demonstrate the x-ray films?

DR. TRACY B. MALLORY: We have the films, but no radiologist is here to interpret them. Perhaps Dr. Hamlin can help.

DR. ALLEN: Where are the cavities that were thought to be abscesses?

DR. EDWARD HAMLIN, JR.: There is tremendous dilatation of the entire biliary tree, especially the intrahepatic portion. The stones lie close to the ampulla. I was never certain about the abscesses.

DR. ALLEN: Are they consistent with the size of the stones removed?

DR. HAMLIN: They are smaller.

DR. ALLEN: At the age of eighteen, the patient had some very serious illness associated with fever and chills and jaundice that lasted for six months and during which his temperature for over a month was about 105°F. During this illness, he had edema, which might very well have been and probably was nutritional edema, because he had been ill a long while. Bloody stools were very probably the result of vitamin K deficiency, which accompanies jaundice of long duration. What that disease was, I do not know. Perhaps one can simply call it severe catarrhal jaundice, or hepatitis, and it probably was not associated with any mechanical obstruction to the extrahepatic ducts. It may have been some generalized disease affecting the liver secondarily. The patient apparently got along well for quite a while after this, and for sixteen years was without complaints. Then he began to have difficulty associated with gas on the stomach, and pain. The description is not too good, but it is probably good enough for me to say that ten years before admission the acute attack described was one of gallstone colic. The patient had indigestion and pain followed by jaundice. This responded well to morphine as pain of this sort does, in spite of all the scientific evidence that morphine causes a constriction of the papilla of Vater and therefore increases the pain and that one should use vasodilators instead. Every practitioner of medicine knows that morphine is the only drug that does these patients any good. The number of cases of the spasm type of pain that are relieved by antispasmodic drugs are very few, but the pain occasionally does respond to such medication, which, perhaps, should always be tried first. Usually, a real case of gallstone colic requires morphine for relief, and a large dose of morphine at that. The fact that this patient was suddenly relieved of pain when he vomited bile is interesting because, with the passage of a common-duct stone, the duodenum may suddenly be flooded with bile, which may be vomited. The morphine that was given for relief might have produced the nausea, but pressure within the common duct could account for it. I do not believe that we have to assume that the common duct perforated into the duodenum at that time, although this does rarely occur. The course was quite uneventful for nearly

seven years after that episode, with only occasional attacks of discomfort that a great many people with gallstones have and live with by dietary measures and accommodation of their mode of living.

Four days before admission, the patient had a strenuous time, apparently, following his trip in the country and began to have severe discomfort. Frequently, gallstone attacks are precipitated by motor trips. Any number of patients will tell you that such trips, as well as fatigue, produce an attack similar to that produced by indiscretion in diet. With the attack, this patient again had a chill, which began just before admission and which I suppose was the typical fever and chill of Charcot that is associated with inflammation in the bile ducts and is nearly always caused by stones.

The positive Murphy sign interested me. I asked a dozen or more students what the Murphy sign was; they did not know, and I meant to look it up but did not have time to do so. Apparently it is described here as tenderness in the epigastrium. I am familiar with Dever's sign, used by the late Dr. Charles A. Porter, which is associated with discomfort on heavy percussion over the right lower chest to indicate disease in or about the liver.

The blood count shows that the patient did not have very much infection at the time he was admitted. The Graham test was said to be positive, although no diagnosis of gallstones was made. The duodenal drainage is interesting in that crystals of calcium bilirubinate were obtained. We are not sure how reliable such a test is. When it is negative, one sometimes finds stones in the common duct, and when it is positive, one sometimes fails to find them. But when the experience has been accumulated, as it will eventually be, we can tell whether it is a 40 to 60 or a 30 to 70 chance. In this case, the test was positive, and stones were removed from the duct. The question arises about the white bile that was obtained and was said to be milky in appearance. It might be that the gall bladder was completely shut off by an old inflammatory constriction and that white bile was present within it. White bile rarely occurs in the common duct. We know that this man did not have a common duct full of white bile because they recovered green bile in the other two specimens. If this was white bile, it must have come from the gall bladder, and it was unusual that they could get it to drain, because one usually finds white bile when the cystic duct is completely occluded; this means that the bile has remained in the gall bladder long enough to have the pigment absorbed. How many weeks

that takes, I do not know, but it probably takes quite a long while.

At operation, the liver was found diffusely scarred, suggesting early cirrhosis. I should think that any person who had been through what this man had twenty-six years before in the way of hepatic fever might very well be expected to have a liver that would appear grossly abnormal.

A large gall bladder covered with adhesions was removed. The record does not say whether the bladder contained white bile or not. The common duct was dilated to a diameter of more than 2.5 cm., a very large common duct, and two pigment stones were removed. We do not know whether these were irregular, very dark biliverdin stones, or bilirubinate stones, which are lighter in color, or yellow cholesterol stones. Perhaps it is not important, but I should expect that they were the biliverdin type because these are much more apt to get stuck in the common duct since they are so sharp, hard and irregular. The ampulla was dilated, and a T tube was placed in the common duct. If one has such a problem and finds that the common duct is 10 mm. in diameter, the right hepatic duct will be about 7 mm., and the left slightly smaller—about 5 mm.; therefore, if one is going to dilate the opening into the duodenum so that the stones can pass that have been pushed back or remain in the liver duct,—and I am sure this happens quite frequently,—one must gently stretch the outlet to a size slightly larger than the diameter of the right hepatic duct. One can measure the ducts accurately with instruments, and if one makes the outlet slightly larger than the right hepatic duct, stones that are overlooked are apt to pass through. We have collected stones from the stools in such cases.

At any rate, this man did well after the operation. The record mentions a fever of 100°F. for a while, and states that jaundice continued for a week or so and that the van den Bergh reaction was higher than that on admission. Decompression of the common duct does relieve jaundice, but it relieves it slowly. It takes just as many days or weeks for jaundice to clear up following decompression of the liver as it does for the patient to acquire the jaundice. If he has been jaundiced for three months, it will require about three months to lose all signs of icterus. This slow recovery does not bother me too much. Possibly, the fever and the increased van den Bergh reaction were indicative of a slight, temporary, acute hepatitis precipitated by this operative maneuver, and I think one might assume that such a hepatitis took place.

The Hippuran injection is interesting in that it shows beyond the T tube two opaque bodies

or areas that could very well be stones in the common duct. A great deal of work has been done on the Hippuran injection of the biliary tree, and many surgeons have advocated performing this test on the operating table. Dr. Charles G. Mixer, who has a good setup for such examinations at the Beth Israel Hospital, believes that it saves re-exploration of many ducts. Mirizzi,<sup>1</sup> of Cordoba, Argentina, has written an excellent monograph on this procedure; he describes many cases in which second operations have been avoided by Hippuran injection done before the patient left the operating table. Our experience in this procedure has not been particularly good. In one case recently,—in which we knew that the patient should have another stone, since we had counted them before and could not find the last one,—we did a Hippuran injection in the operating room; the x-ray plate showed the duct all clear, the dye going into the duodenum without incident, but a week later, when we repeated the test, there was the stone outlined beyond the T tube just as clearly as these two shadows shown here. The stone may hide itself in the liver ducts and then may come down with the current of bile without passing through the papilla of Vater. I suspect that is what took place in this case. It may be a mysterious and peculiar situation, but as the history is given, I believe that that is what this man had. I do not believe he had any of the bizarre or peculiar situations that sometimes produce symptoms and signs that are similar to those of common-duct stones.

I believe that the second admission was probably due to bile peritonitis. The patient had lost the T tube two weeks before he came back. His last illness was precipitated by a very sudden onset of discomfort, and on examination with the stethoscope he was found to have a silent abdomen. Since the T tube had come out of the duct and the external wound had thoroughly healed, one could visualize that, with stoppage in the common duct due to stone in the region of the papilla, the patient might well have opened up the old incision in the common duct and developed a bile peritonitis. It is obvious that intestinal obstruction was considered, because a Miller-Abbott tube was passed. It is quite possible that the patient had something else to explain this very acute upset that brought him back to the hospital, but it certainly suggests bile peritonitis.

Bile peritonitis is quite a dangerous condition, and in 18 cases that we have had in this hospital in a period of ten years, the mortality was 22 per cent.<sup>2</sup> That is lower than it is in most clinics. McLaughlin<sup>3</sup> has recently published an article on bile peritonitis and collected what he could from

the literature on the subject. His mortality percentage ranged between 40 and 60 in various hospitals. In this clinic, it is low because we have learned that early recognition and early operation are indicated.

This man survived whatever this acute episode was for four days and was reoperated on; I should expect to hear that bile peritonitis was found at this operation and that very probably they were able to remove more stones from the common duct when they explored it.

Dr. HAMILIN: I operated at the first operation. Dr. Allen has described exactly what the situation was, and the subsequent events. At operation we found a very large common duct. We could palpate the stone close to the ampulla. After we had opened the common duct, we explored the hepatic ducts before we took out the obvious stones, to obviate the loss of stones above. We found none. We took out the two stones, dilating the ampulla, but probably not enough. The patient seemed to be doing well until the illness described took place. I did not see him on the second admission, except when he was operated on, and at that time the surgeon opened into a large abscess cavity of bile peritonitis, which was apparently rather tightly walled off. The surgeon believed that the patient was too ill for the common duct to be explored at that time. Drains were put in the abscess cavity, and for two or three days he was quite well and his drainage decreased very much, although he did have some bile in the stools and in the intestinal contents. He finally developed a hepatorenal syndrome, and died in apparent renal failure.

Dr. ALLEN: This is interesting because it is very difficult to prevent an external biliary fistula. An external fistula will break through the incision even if it is two or three weeks old, or bile will come through an old drainage tract, in almost every case. The Medical Service studied an interesting patient about six months ago—a woman who had had a cholecystectomy elsewhere shortly after delivery of her first child. She was about twenty-three years of age. She did badly after the operation and was re-explored in the hospital where she had had the original operation, and at this time they made a new incision. Both these incisions healed; the patient still did badly and after three months came to this hospital with a tremendously swollen abdomen. She had fluid in the abdomen, jaundice and a very high prothrombin level, and when they tapped her abdomen they obtained bile. When we explored her, we found that the common duct was communicating with a huge false sac, which filled almost the whole peritoneal cavity. We were able to pick up the proximal end

of the common duct and re-establish continuity with the intestinal tract. It is very unusual for anyone to survive confined bile leakage for such a long time. In every other case, in my experience, in which the patient has survived any length of time, bile has forced its way to the surface through the old drainage tract or through the incision.

#### CLINICAL DIAGNOSIS

Common-duct stone, with obstruction and probable bile peritonitis.

#### DR. ALLEN'S DIAGNOSES

Choledocholithiasis.  
Cholangitis.  
Bile peritonitis.

#### ANATOMICAL DIAGNOSES

Choledocholithiasis (intrahepatic).  
Cholangiectasis.  
Biliary cirrhosis.  
Focal acute hepatitis.  
Bile peritonitis.  
Chronic pancreatitis, with fat necrosis.  
Pulmonary infarcts, bilateral.  
Icterus.  
Bile nephrosis, slight.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: At autopsy, an extensive bile peritonitis was found. We were unable to demonstrate any actual communication between the peritoneal cavity and the biliary-tract system. Undoubtedly, a fistula must have been present, but it had apparently more or less closed off and certainly was not widely patent at the time of autopsy. The common duct did not contain any stones. However, in the duodenum just beyond the papilla we found a stone that we may have forced out of the common duct in manipulating the tissues. In contrast, when we followed the ducts up into the liver, we found the biliary radicles enormously dilated, as one sees in the x-ray film, and many stones within them, more than a dozen. The remainder of the liver was scarred and tough, and showed an unusually severe grade of biliary cirrhosis. In fact, I cannot remember having seen a liver in which there was so much collagen surrounding the bile ducts. In a localized part of the liver, there was also acute infection of the smaller bile ducts, many polymorphonuclears and some organisms being visible in the sections. So that there was a localized acute hepatitis, as well as old chronic biliary cirrhosis, but no gross abscess.

It is interesting, when one considers the death from apparent uremia, that the kidneys showed

virtually nothing. There was, as there always is, a slight degeneration of the tubules, so-called "bile nephrosis," which is invariable with chronic jaundice, but it is difficult to see how that per se would affect function of the kidney. I should be inclined to consider this primarily a case of liver failure rather than one of renal failure.

DR. ALLEN: I wish someone would tell me what the disease was that the patient had at the age of eighteen when he was ill for six months.

DR. MALLORY: There was nothing at autopsy by which we could say. It is conceivable that it was cholecystitis and cholangitis even at that time, since the fibrosis within the liver was so extremely dense and old.

DR. JAMES A. HALSTED: Do you think that it could have been typhoid fever, with localization in the gall bladder and subsequent formation of stones?

DR. MALLORY: That is conceivable. The gall bladder was not cultured at the time of the first operation.

#### CASE 28122

#### PRESENTATION OF CASE

A forty-six-year-old Greek leather worker was admitted to the hospital because of pain in the left knee.

The patient was well until nine months before entry, when he noted pain and swelling in his left knee that became gradually severer. The pain was most marked over the sides of the knee. There was little limitation of motion until two weeks before entry, when the knee became stiff, interfering with walking. There were no chills, fever or other symptoms, except slight malaise.

The past history was irrelevant. The patient had never had gonorrhea.

On admission, the patient appeared swarthy, heavy-set and in no acute distress. The left knee was swollen and hot. A mottled, brownish skin discoloration over the knee suggested previous application of heat. There was tenderness over the medial and lateral tibiofemoral fossas, more marked over the medial. The knee was held in 15 to 20° flexion, and only 5 to 10° more flexion was possible without extreme pain. The patella was not ballotable, but there was questionable fluctuation of the soft parts at each side of it. A lymph node 3 cm. in diameter was palpable in

the left groin, and one about 2 cm. in diameter in the right groin, neither being tender. There were no other positive physical findings.

The temperature was 99°F., the pulse 80, and the respirations 20. The blood pressure was 130 systolic, 90 diastolic.

Examination of the blood showed a red-cell count of 4,480,000 with 13.2 gm. hemoglobin, and a white-cell count of 5200 with 61 per cent polymorphonuclears. The blood Hinton reaction was negative on two occasions. The sedimentation rate was within normal limits. The urine was normal. A skin tuberculin test was performed, but the result was not recorded on the chart.

Roentgenograms of the left knee showed a finely granular area of calcification along the lateral margin of the right knee joint close to the region of the capsule, but extending downward and backward to the head of the fibula. There was indefinite follicular calcification just above the head of the fibula in the lateral view. There was a small amount of fluid in the upper recess of the knee joint. An area of diminished density 1 cm. in diameter appeared in the medial portion of the tibial eminence. No definite soft-tissue mass was seen.

Aspiration of the knee joint gave slightly cloudy, orange synovial fluid, with a viscosity of 9.9 and a normal mucin content. The fluid contained 11,550 red cells and 1150 white cells per cubic millimeter, with 6 per cent polymorphonuclears, 62 per cent monocytes, 22 per cent lymphocytes and 10 per cent clasmotocytes.

On the fifth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. CLAUDE E. WELCH: It appears that stiffness of the knee rather than pain was the factor that brought this patient into the hospital. There is no mention of any previous inflammatory lesions, such as boils, that would suggest a secondary inflammatory lesion of the bone.

It is of some interest that no distinct mass was palpable.

It is interesting that the men in charge considered it unnecessary to do other blood chemical studies.

May we see the x-ray films?

DR. GEORGE W. HOLMES: I can point out only the things that are indicated in the text—the area of calcification and the soft-tissue changes described. Here is the area of diminished density in the region of the tibial tubercle. In the lateral view, this area is not visible. The area of increased density in the soft tissue seems to lie posterior to the head of the tibia and below the fat

layer, in the muscular layer or in the margin of the capsule. It is important to know whether it is in the capsule or in the soft tissue just external to the capsule. I should say it was external, but that is a guess. In addition, there is some questionable thickening in the region just above the patella and a questionable increase in width of the joint space; this is suggestive of fluid, but there is no positive evidence of fluid. There is no bone atrophy, no evidence of spur formation about the condyles, nothing to suggest arthritis of the ordinary type, and nothing to suggest a chronic lesion like tuberculosis. So that from our point of view we have two things: an area of diminished density in the tibial tubercle, and an area of calcification in the soft tissues, neither of which I can explain.

DR. WELCH: I am interested that they term this spot "follicular calcification." Does that mean anything to you?

DR. HOLMES: It means that it was laid down in small flecks instead of masses.

DR. WELCH: I must admit that the findings of the aspirated knee-joint fluid mystified me, so that I asked one of our orthopedic experts about it. He said that he also was mystified, and we called the technician. I am not sure that I quote her correctly, but if I do, the fluid was thin, the normal mucin content being against arthritis. So far as the cell count is concerned, there is evidence against any type of septic joint, and that is as far as one is justified in going.

I shall mention the commonest lesions that may be expected in the knee joint and indicate the ones we can rule out. I have written them down in a more or less unclassified fashion. Could this be a metabolic disease, such as gout? There is no information, so far as the blood uric acid is concerned, and it is very unusual to have a single joint involved. Also, the history is not very typical. There were no severe paroxysms of pain. Could it be a Charcot's joint? Obviously not, according to the x-ray picture. Could it be tuberculosis? Dr. Holmes has remarked about the atypical features of the x-ray film so far as tuberculosis is concerned; clinically, this does not suggest a tuberculous joint, which usually appears in an old person and is very painful. Could it be any of the various specific forms of arthritis, such as infectious arthritis? That would be very unlikely, since the articular surface was essentially normal. Gonorrheal arthritis is excluded on the same basis. Could it be rheumatoid or hypertrophic arthritis of the joint? The x-ray picture is against it. We have nothing in the knee tap that would specifically suggest that diagnosis.

Could it be osteochondritis dissecans? I think we can eliminate that by the x-ray picture.

We are reduced, it seems to me, to two lesions: an inflammatory lesion of the nature of a Brodie's abscess that had not involved the knee joint, and some type of tumor located just below the synovial capsule. The calcification in the lateral margin of the knee joint, whether in the capsule or external to it, was there for a certain length of time,—no one knows how long,—and I do not believe that we have any definite right to say that this area of calcification is significant, although it is possible. Then, can we call this an inflammatory lesion or tumor? If inflammatory, it was an inflammatory lesion with no temperature, no elevated white-cell count, normal sedimentation rate, normal differential count and an aspirated fluid

diagnosis, and I shall say tumor of the knee; I do not care to be more specific concerning type.

DR. S. P. SARRIS: We had quite a discussion about this patient. A great many people looked at the x-ray films, and I discussed the case with most everyone in the X-ray Department and several members of the orthopedic and surgical staff. We were stumped for a diagnosis, and I consulted on this patient with Dr. Otto E. Aufranc, with the hope that between us we might be able to handle the surgical and orthopedic lesions of this area. I operated with the preoperative diagnosis of Brodie's abscess at the upper end of the femur. We had previous x-ray films, and it seemed to me that the area had increased since the first films were taken. Dr. Aufranc, I believe, favored the

FIGURE 1. *Foci of Hyaline Cartilage Developing in the Synovia.*

that is not compatible. In other words, I am definitely inclined against the diagnosis of an inflammatory lesion, and I am inclined toward the diagnosis of tumor.

Suppose it is a tumor, what lesions could simulate this x-ray picture? That again is extremely difficult, because the x-ray film is not typical of any one of them. Primary tumors in that location are limited to osteogenic sarcoma of some type or synovioma, a primary tumor of the knee joint. The picture is not typical of a metastatic lesion except for the destruction of bone. It is hard to explain the area of calcification along the lateral margin of the joint on the latter basis.

It may seem that I have talked myself out of everything, but I must go on record as making one

diagnosis of aseptic necrosis of bone. At operation the knee joint was opened, and presented the strangest sight I have ever seen. It was packed with split-pea-sized pearly masses that were firm but also elastic. Many of them were completely free of attachment to any of the normal structures of the joint, whereas others were embedded in the synovia or attached to it by the pedicle. I estimated there was about 200 cc. of solid material. It was all removed, and a synovectomy was performed.

DR. WILLIAM B. BREED: When you finished the operation, what was your diagnosis?

DR. SARRIS: At that point, we still did not know what it was. We called over the pathologist, Dr. Walter Bauer and a few others, and

after seeing the knee joint open we still did not know what it was.

#### CLINICAL DIAGNOSIS

Traumatic synovitis, left knee.

DR. WELCH'S DIAGNOSIS

Tumor of the knee joint, unspecified.

#### ANATOMICAL DIAGNOSIS

Chondromatous metaplasia of the synovia of the knee joint.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The joint, as Dr. Sarris has explained, was completely filled with gristly material that proved on microscopic examination to consist almost entirely of cartilage. The cartilaginous foci formed within the synovia, as one can see from the photomicrograph (Fig. 1). The synovial mesothelium is at the top of the picture, and one can see that immediately beneath it are multiple round masses of varying size, each of which is a little focus of hyaline cartilage. The deposits are of varying age, some of them obviously freshly formed, whereas others must have been present for a long time, since they are partially calcified. When these foci arise in the synovial villi, they hang by narrow pedicles into the joint cavity, frequently break off and become

joint mice. They continue to contain living cartilage cells. We have had one other case of this sort. In another possibly related case, the synovia was entirely replaced by chondrosarcoma, so that I suspect the cartilage can and occasionally does degenerate into malignant tumor. I should term the process chondromatous metaplasia of the synovia. There does not seem to be a great deal written about the condition, although Jones\* reported 19 cases in 1924 from the Mayo Clinic. Its etiology is entirely unknown.

A PHYSICIAN: Are you surprised that the x-ray film did not show more?

DR. HOLMES: One would not expect it to.

A PHYSICIAN: What is the prognosis?

DR. MALLORY: Perfectly favorable.

DR. HOLMES: How did you explain the area of diminished density?

DR. SARRIS: I was going to add that, at the time of the operation, there seemed to be a mass of these nodules pressed between the two joint surfaces overlying this area, and we interpreted it as aseptic necrosis from pressure atrophy.

DR. MALLORY: The only point on which the various consultants who saw this patient before operation agreed was that diagnosis was impossible without biopsy.

## NEW LAMPS FOR OLD

SHORTLY after John Brown's ill-fated raid on Harper's Ferry, Henry Thoreau, impressed by that gallant fiasco, felt the need of doing something about it, of allying himself with a cause, no matter how fantastic, in whose spirit he believed. Against the advice of friends, he hired a hall, announced a mass meeting, and delivered an address in which he advanced the theory that we as a nation had used up our inherited liberties. Just as our other inheritances may eventually become depleted through taxation, dispersion and poor investment, so today, according to Thoreau's theory, we may again be said to have exhausted our stock of passively acquired freedom.

The Civil War was a crusade to reaffirm a nation's belief in democracy—in the viability of various bills of rights under which free people might live. This belief was reaffirmed in 1861 and is today once more undergoing a trial ordeal. This trial, to which we have been subjected for the last decade and which has reached its crucial period, concerns the fitness of a people to assume the obligations as well as to enjoy the benefits of their liberty.

Liberty, which is basically a spiritual thing, can be interpreted as a very material thing when the need for testing it has arisen. This shore was settled largely by people who sought spirituality, who strove for it, and who passed it on to their descendants. As the rich resources of the land came to the surface, the acquisition of wealth that could be chemically assayed became a universal goal, and liberty came to be interpreted as the right to acquire that wealth in unlimited quantities.

This inherited liberty is in its turn being used up, and a present generation must find its freedom, for it is surely losing the old. The day on which material goods are being destroyed, and the rate at which the wealth of a nation is being consumed, must make us acutely aware that the end of our present system of utilizing liberty is in sight, and that the era of passive exploitation is over.

The "American way of life" that we are fighting for must have a very different meaning from that which can be so easily read into the words of this phrase. If by the American way of life we mean the exploitation of the land for individual gain,—a universal and perpetual struggle in the pursuit of a dollar of easy virtue,—the American way of life is not only indefensible, it has already vanished around the corner. If, however, by the American way of life we mean the safeguarding to each of the opportunity to work out his own destiny, if we mean a personal and national adaptability that will see us through the profound changes that are to come, we are in a fair way to construct a new liberty for our generation.

## HOSPITAL FACILITIES

The Bureau of the Census of the Department of Commerce has recently released what it describes as "the most widespread survey ever made of hospital bed facilities in the United States."<sup>1</sup> In the release, figures are given for the year 1939, and they seem to be largely interpreted in terms of the "minimum requirements for adequate medical service," as set up in 1933 by the Committee on the Costs of Medical Care. The figures are then broken down into three groups according to the total number of beds per population unit for each state. Thus, four states, including Massachusetts, and the District of Columbia are said to have good facilities, and eighteen states to have adequate facilities; the remaining twenty-six are classified as having inadequate facilities.

Just what the Bureau means by the "most widespread survey ever made" is not clear. Six months previously, the American Medical Association<sup>2</sup> released its annual register of hospitals, listing at least 1,304,628 beds and bassinets (against the Bureau's stated 1,282,785 beds). The Bureau's release is also vitiated by its failure to consider its subject qualitatively. The only criterion used is the ratio of beds to population, and on this alone it passes judgment that more than half the states have inadequate hospital facilities. The Bureau implies that 2000 more 170-bed hospitals are needed in this country. This may appear necessary to some politicians, but of greater fundamental importance is the need for improving existing hospital facilities, so that more of the present beds can be approved by the American College of Surgeons and by the Council on Medical Education and Hospitals of the American Medical Association. This would mean not only a great increase in laboratories and equipment, but an even greater increase in trained man and woman power. The lack of quality and efficiency in hospitals is even greater than the lack of beds, and is less easily remedied. Of the hospital beds investigated by the American Medical Association, only a half were in hospitals approved by the American College of Surgeons and only a third were in hospitals ap-

proved for internships, residencies and fellowships by the American Medical Association.

If the Bureau of the Census is going into these matters, it appears that professional advice should be employed. It, of all governmental departments, should be up to the sixteenth (1940) census by now. The subject is too important to be discussed in any but the most enlightened and up-to-date manner. There is a war to win before the Nation returns to the political connivances of 1939.

## OBITUARY

### SOMA WEISS

1899-1942

Doctor Soma Weiss, Hersey Professor of the Theory and Practice of Physic at Harvard University and physician-in-chief of the Peter Bent Brigham Hospital, died suddenly on January 31, 1942, at his home in Cambridge, Massachusetts, aged forty-three years. Death was caused by a subarachnoid hemorrhage.

Doctor Weiss was born in Besterce, Hungary, on January 27, 1899, and came to the United States in 1920. Early in life, he showed great interest in scientific research and, while attending the Royal Hungarian University in Budapest, received the appointment of demonstrator and research fellow in physiology and biochemistry. This interest in fundamental research continued in an uninterrupted manner. In 1920, he became an assistant in pharmacology at Cornell University, and during this period, he made fundamental observations on the mechanism of vomiting and the action of digitalis. In 1921, he received his Bachelor of Arts degree from Columbia University, and two years later, graduated from Cornell University Medical School. Following an internship at Bellevue Hospital, New York City, he joined the Department of Medicine of Harvard Medical School as a member of the staff of the Thorndike Memorial Laboratory of the Boston City Hospital, at first under the direction of Dr. Francis W. Peabody and later under that of Dr. George R. Minot. While associated with the Boston City Hospital, he became assistant director of the Thorndike Memorial Laboratory and, later, director of the Second and Fourth Medical Services and chief of the Fourth Medical Service. He remained there

until 1938, when he was appointed physician-in-chief to the Peter Bent Brigham Hospital and Hersey Professor of the Theory and Practice of Physic at Harvard University.

Doctor Weiss was a member of many medical and scientific societies, including the American Society for Clinical Investigation, Association of American Physicians, American Heart Association, American Academy of Arts and Sciences and American College of Physicians. He was a member of the Council on Pharmacy and Chemistry of the American Medical Association, and took an active interest in the Massachusetts Medical Society and in many problems concerned with national defense.

His interests in medicine were extremely broad, but he was especially well known for his work in cardiovascular disease and in clinical pharmacology and therapeutics. Starting with a study of the velocity of blood flow with Dr. Herrman L. Blumgart, he devoted his attention to such problems as hypertension, carotid-sinus disorders, syncope, shock, beriberi, heart disease and chronic pyelonephritis. Shortly before his death, he published, with Dr. Lewis Dexter, a monograph entitled *Toxemias of Pregnancy*. All his writings reflected his interest in seeking the truth, which led him into a careful and patient search for scientific facts concerning the problem at hand. He was always subjecting his ideas and thoughts to investigation and experiment. Problems that were constantly arising on the wards were transported to the laboratory for solution. "How" and "why" were two words that he used frequently in the discussion of medical problems.

He had a number of pupils who now hold important posts in academic medicine in this country and abroad. His guidance and stimulus were an invaluable asset to them.

Here was a man with a profound knowledge of medicine, a keen sense of humor and the courage of his convictions, combined with a great kindness and consideration of others. The memory of Soma Weiss and his achievements will always remain in our hearts and in the record of his short but striking and productive career. As Tennyson remarked, "Tho much is taken, much abides."

C. S. K.

## MEDICAL EPONYM

### DE MUSSET SIGN

The de Musset sign of aortic regurgitation was described, not by a physician, but by Paul de Musset (1804-1880), brother of the poet, in his *Biog-*

*raphie de Alfred de Musset; sa vie et ses oeuvres* [Biography of Alfred de Musset: His life and his works] (Paris, 1877). The following translation is from pages 274 and 275:

The illness so well cared for by Sister Marcelline had left him with a troublesome tendency to affections of the chest. . . . We called the doctors twice during the course of the winter; they bled him too often.

Whatever they may say, I am convinced that their lancets caused him irreparable harm. At breakfast one morning in March, I noticed that my brother's head was bobbing involuntarily with each pulse beat. He asked my mother and me why we were looking at him with such a startled air. We told him what we saw, and he said, "I did not think you could see it; but I will reassure you."

He made some sort of pressure on his neck with his index finger and thumb, and in a moment his head stopped marking his pulse. "You see," he then said to us, "that this dreadful illness can be cured by simple and inexpensive means."

We were reassured, being ignorant, for we had just observed the first symptom of a grave malady to which he was to succumb fifteen years later.

R. W. B.

CASE HISTORY: ABLATIO PLACENTAE,  
ASSOCIATED WITH HYSTERECTOMY AND  
FOLLOWED BY DEATH

A twenty-four-year-old para III was admitted to the hospital with a diagnosis of ablatio placentae. The past history was irrelevant. The two previous pregnancies had been terminated by cesarean section, the reason for the first section not being known.

The patient had had no prenatal care except for one visit to a physician at the beginning of the eighth month. When nearly at term, she began to bleed and summoned her physician, who made the diagnosis of internal concealed hemorrhage and immediately sent her into the hospital. Her condition on arrival suggested severe intrauterine hemorrhage. The uterus was firm, the fetal heart was not audible, and the patient was not in labor. Soon after admission, the vagina was packed with gauze. External bleeding became profuse. Two thousand cubic centimeters of 10 per cent glucose was administered intravenously, and was followed by transfusions totaling 3000 cc. of citrated blood. In spite of these measures, external bleeding continued, and a laparotomy was performed seven hours after the patient entered the hospital. The fetus and uterus were removed. The day following operation, the patient became

edematous, developed edema of the lungs, and died, presumably of cardiac failure

*Comment* Inadequate prenatal care may have been responsible for this death. There is no record of the findings when the patient was seen once at the beginning of the eighth month. It is probable that had she been seen again after this visit, increased blood pressure and albuminuria would have been recognized. In view of the two previous cesarean sections, unless this patient was practically moribund when she entered the hospital, it is likely that a laparotomy immediately on entrance, preceded by transfusion, would have averted this catastrophe.

The generalized and pulmonary edema that appeared the day after operation may well have been caused by the tremendous amount of fluid that this patient hid. If not, the edema and cardiac failure were due to the cardiac asthma so frequently seen in crises of toxic separation of the placenta. If the patient's condition on arrival was so serious that laparotomy was contraindicated and conservatism seemed the only intelligent treatment, the cervix as well as the vagina should have been picked and a Spanish windlass applied. This method should have been adopted only as a last resort, with the knowledge that rupture of the uterus from the previous cesarean sections was always possible.

The record does not state that the hysterectomy following the cesarean was necessitated by a uterus that would not contract. This does happen in patients with a completely separated placenta, and the only way to control the bleeding is to remove the uterus. On the other hand, if it is not imperative to remove the uterus in a patient in such poor condition, hysterectomy is certainly a more serious operation than cesarean section and hence is contraindicated.

#### THE ROLE OF THE MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH IN CIVILIAN DEFENSE\*

Recently, several persons have asked me what part the Massachusetts Department of Public Health plays in the National Defense Program. They went on to say that although they have frequently read and heard about the plans of other agencies, they have rarely come across any mention of the Department of Public Health.

The answer to this is that the Department of Public Health as part of its everyday duty, must always be prepared to deal with emergencies that may affect the public health such as epidemics, floods and hurricanes. Being always prepared for emergencies, I suppose we have more or less taken it for granted that the public would realize our effective participation in the defense program.

Twice within the past ten years, we have been called

on to function in times of disaster of natural origin. The flood of 1936 in the Connecticut and Merrimack valleys and the hurricane and flood of 1938 are still fresh within the memories of all of us, although their magnitude and importance pale when compared with the enormity of the present problem. In both emergencies, the facilities of the department were readily made available to the distressed areas. In general it may be said that in the present crisis we shall function according to a state plan, which was drawn up after the flood of 1936 and revamped in 1940 to include all state and allied agencies that must be called on to render aid during any major emergency.

It can be considered that the Department of Public Health has two parts to play in the present defense effort. The first, and perhaps the more dramatic part, is our role in the State Emergency Plan. On receipt of official notification of a possible disaster, the specialized personnel in the Massachusetts Department of Public Health report for duty at their assigned stations. On this official notification, many of our workers will report to various armories throughout the State, where they will function in close co-operation with the State Guard and various local organizations. The department is providing for two first aid rooms in the State House for the care of State House personnel in time of disaster.

Our principal problem is to maintain public health practices at the highest possible level of efficiency, for it is in times of disaster that such practices are most seriously threatened. Our staff members, through the various armories, are readily available to render advice, guidance and assistance in the many public health problems that may arise. For example, the engineers may be asked to assist in a matter concerned with water supplies or sewage disposal. Military catastrophes of one type or another are quite apt to have a damaging effect on water supplies and sewage disposal systems. Modern sanitary engineering has been perfected and developed so that in our time typhoid fever and other intestinal infections have been reduced practically to a minimum. Any interference with these systems must be instantly coped with and for this reason our state engineers have staffed their field personnel in even smaller districts than the other divisions have.

If pollution of a water supply should occur, engineers would be immediately on hand to assist the water boards and water companies in taking whatever steps are necessary to render the water supply safe. Emergency chlorine and chlorinator depots are distributed strategically throughout the State to supplement the reserves of local communities. Engineers and inspectors are ready to assist in obtaining specimens for laboratory examinations to ascertain whether or not the water supply is safe. We have obtained the co-operation of local laboratories for emergency examination of such specimens in case it is impossible to forward them to the departmental laboratory.

Similarly, the engineers, together with the co-operating local agencies, are prepared to remedy disruptions in the sewage systems, since these disruptions may result in the pollution of water supplies and consequently in the possible spread of disease.

Our district health officers will undoubtedly be asked to co-operate in ascertaining whether or not epidemic conditions exist or threaten and, if so, how they can be brought under control. They may be asked to help in ruling out communicable diseases among possible evacuees and frequently in emergencies are asked whether or not preventive inoculations of one type or another are indicated.

Our supervisor nurses will be available to local health departments and visiting nurse associations in meeting

\* A. Green gives to Health broadcast given through Station WAAF by Dr. Paul J. Jakubczak on Saturday, January 17, and sponsored by the Public Health Council of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

the problems of carrying out a generalized program under extremely difficult conditions.

Our nutritionists will be acquainted with the whereabouts of reserve food supplies and are skilled in such things as emergency feedings and the mechanics of setting up canteens.

Food inspectors and sanitary officers are always in demand to pass on whether this food can be used or that food should be condemned. Laboratories are distributed throughout the State in such a way that it can be immediately learned whether or not milk or food has been endangered by possible contamination.

Our medical social workers will undoubtedly be asked to bring to bear their comprehensive knowledge of community resources and of how they can be marshaled to effect a solution in any particular emergency.

It can readily be seen that to have units established in certain key armories will facilitate bringing to any part of the State the entire services of the Department of Public Health with a minimum of delay. From time to time, it is possible that certain key individuals might be released from armory assignments to work with other agencies in meeting particular problems that may arise. We must remember, however, that the first duty of the department is to make it possible for state services to reach into all corners of the State. We cannot limit our plans to any particular city or district. Every possible effort is being expended for the closest co-operation between our personnel and the splendid and comprehensive program worked out for this particular emergency by the Committee on Public Safety. For example, our State district health officers, of whom there are eight and who act as the official representatives of the Commissioner in their districts, have been designated by the committee on public safety as regional directors for health. In this respect, they have been of assistance in the formation of many local city or town committees, and have also assisted such committees in developing the desired program.

Our division directors keep in close touch with the policies and plans of the various subcommittees of the Massachusetts Committee on Public Safety, particularly those dealing with health and sanitation. In this way, the activities of our specialized personnel can be correlated and integrated with those of the state committees. Other members of our department are working in conjunction with the aforementioned committees on such things as emergency housing, evacuation hospitals and similar problems.

What I have said thus far constitutes our first role in national defense. I should like to dwell a few moments on our second role, which, although it may be less dramatic, is nonetheless significant. The so-called "home front" is always of importance in war, but particularly is this true at the present time. It is universally admitted that a continued uninterrupted flow of ships, tanks, planes and guns from the shipyards, arsenals and factories is an absolute necessity in the successful conduct of this war. That this stress of production may be uninterrupted, the public health must be kept at an unusually high level. It is at times such as this, when all are more or less overfatigued and continually busy about other things, that health may be allowed to become impaired. We must be on our guard to keep "sound minds in sound bodies." The children of today are the men of tomorrow, and the men of tomorrow are quite apt to be soldiers. We must profit by the lessons learned in the recent draft and put into effect all possible measures that will cause young men to appear before the Selective Service boards in the

best physical condition. Similarly, the health of workers in industry must be protected and preserved, lest fatigue, malnutrition, respiratory disease or other disease be allowed to decimate industrial ranks and seriously interfere with production.

During the anxious days ahead, we must continue to throw every protection and safeguard about women and children. From a health point of view, no effort must be relaxed toward keeping our communities safe. Health-education measures designed to promote better nutrition must go on. The conditions of war, overcrowding, hunger and exposure, although fortunately not prevalent in this state, must be anticipated. Such conditions are the forerunners of epidemics. Because disease itself is absent from our midst at the present time does not mean that the bacterial causes are not always present, awaiting only suitable soil.

The second role that the Department of Public Health plays, then, is this critical one of making absolutely certain that the ground gained in the war against disease is not lost in the present crisis. Even though we were absolutely safe from bombing and sabotage, I should consider this maintaining of the public health to be an extremely vital assignment. This is, of course, not the responsibility of the Department of Public Health alone. Each local board of health is alert to the responsibilities, and plans to carry on in the future as in the past. The voluntary agencies are likewise mindful of their responsibility, and I can assure you that through the co-operative effort of all concerned, health standards will be maintained.

I shall now summarize briefly the dual role of the Massachusetts Department of Public Health in national defense. In the first place, it is prepared to bring to bear in any affected area in the State specialized personnel equipped and capable to cope with any situation. Such personnel will function out of certain key armories in close co-operation with the State Guard, local civilian-defense committees and local health departments. Secondly, it is alert to the need of maintaining health standards even in the absence of air raids and sabotage, and is gearing its efforts to cope with this very real, if less dramatic, duty.

## DEATH

LADD — MAYNARD LADD, M.D., formerly of Boston, died March 9. He was in his seventieth year.

Born in Romeo, Michigan, Dr. Ladd received his degree from Harvard Medical School in 1898. He was formerly a member of the faculty of Harvard Medical School, director of the preventive clinic at Boston City Hospital, chief of the children's department of the Boston Dispensary and president of the American Pediatric Society.

He is survived by two daughters.

## WAR ACTIVITIES

### CIVILIAN DEFENSE

#### NURSING SERVICE FOR THE WAR

Nursing service is being rapidly organized to take its place in the civilian-defense program. A full-time nursing consultant is on duty as a member of the staff of the Medical Division of the Office of Civilian Defense in Washington, and the Subcommittee on Nursing of the

Health and Medical Committee of the Office of Defense Health and Welfare Services also serves as the Nursing Advisory Committee of the Office of Civilian Defense. Through the consultant and the advisory committee the Medical Division is in contact with all federal agencies that have nursing programs and the Nursing Council on National Defense, which represents national nursing organizations, the Red Cross and federal agencies. To assist the regional civilian-defense offices in interpreting the emergency medical service program, field nursing consultants of the United States Public Health Service, the United States Children's Bureau and the American Red Cross have been made available for consultation. One nurse representing the Red Cross and another representing one of the other two agencies have been assigned to each state.

The most recent development in the nursing program is the establishment of state nursing councils. These councils are made up of representatives of nursing organizations, official agencies with nursing programs and the Red Cross. It has been recommended by the Medical Division of the Office of Civilian Defense that the services of these state councils be made available to state defense organizations.

Nursing representation on local medical advisory councils has also been recommended by the Medical Division of the Office of Civilian Defense, and local nursing councils are being formed throughout the country.

Nurses are required in the emergency medical service now being developed by the Medical Division of the Office of Civilian Defense. They will be needed not only for the care of casualties in hospitals but for service with medical first aid posts. If it is necessary to discharge patients from hospitals earlier than usual to make room for war casualties nursing service may be necessary for such patients in their homes. For this purpose, the organizations in the community having public health nurses will co-operate in meeting the needs for providing home care. Nurses will also be required for service in base hospitals, to be established in protected rural areas if needed for the reception of civilian casualties due to enemy action.

Other phases of the work of nurses in civilian defense are the training programs now being carried out in collaboration with the Red Cross. Both the Office of Civilian Defense and the Red Cross are urging promotion of the nurses aide program. One hundred thousand must be trained in the next few months to assist nurses in casualty receiving hospitals and in field casualty services. Nurses are being urged by the Medical Division to arrange to teach home nursing courses, so that more women will be ready to care for sickness in their own homes during an emergency and relieve the hospitals of some of their load. Nurses are also asked to take Red Cross first aid courses so that they may be prepared to help in casualty services and also to qualify as instructors for first aid courses.

and observation at the bedside. The influence of the nervous system on functional and organic somatic disturbances is not a recent psychiatric discovery. It has been known for decades that certain psychic and emotional states are the sole cause of general and local functional disorders, and quite often exciting causes in organic affections. An emotional upset quite frequently precipitates an attack or intensifies the symptoms of gallstone colic or of angina pectoris. In the latter condition it is as potent a factor as physical exertion. But the essential causes of these diseases are the structural changes in the organs, and very few physicians would view them as psychiatric in origin. The same holds true regarding ulcerative colitis.

Mucous colitis is a comparatively rare affection, and spastic colitis, — or more accurately, a spastic colon, for there is hardly any colitis in this condition — a very common one, whereas ulcerative colitis is less frequent than the spastic colon and much more frequent than mucous colitis. Ulcerative colitis begins rather suddenly with blood and bloody mucus in the stools in some cases, it is preceded for a week or more by rather intense diarrhea, but in no case to my knowledge has there been any antecedence either of mucous colitis or of a spastic colon.

Ulcerative colitis is a chronic disease characterized by remissions and acute exacerbations, the remissions lasting from weeks to years. Patients with this affection have financial, economic and social worries and conflicts just as well as people with a normal colon. These worries and conflicts may be factors in acute exacerbations, but their absence, in my experience, is no factor in the remissions, which are due to the natural course of the disease and not to any psychiatric treatment per se. The personality of patients with this affection is, to my mind, about the same as that of persons with any other bodily disease or that of what we call normal people, although some colitis patients may well belong to the giver uppers. When a patient has about twelve to thirty evacuations, and rather painful ones, in twenty four hours, one would hardly expect him to be jovial and optimistic, and it would be rather surprising if he should not eventually become a 'giver upper'. Some clinicians maintain that there is no difference between the functional and the organic, and this is perhaps theoretically true. The concept of body mind has a strong philosophic appeal but the dualism of body and mind is eminently pragmatic, and there is at least some difference between multiple sclerosis and psychoneurosis accompanied by various organic disorders.

Ulcerative colitis is a severe organic disease characterized by remissions and exacerbations. Mental and emotional factors are of importance in its symptomatology, as they are in any other organic disease, but as to its being psychiatric in origin and pathogenesis this view, to my mind, is purely scholastic and a return to medieval mysticism.

LOUIS FISCHBLIN, M.D.

Boston

#### SEROLOGIC TESTS FOR SYPHILIS

*To the Editor* The necessity of serologic tests for syphilis as part of the examination of applicants for marriage licenses and the short time usually available to such applicants as are in military service is not infrequently subjecting the Wassermann Laboratory of this department to adverse criticism. We believe that a statement of the circumstances should demonstrate that such criticism is unjustified.

#### CORRESPONDENCE

##### PSYCHIATRIC ASPECTS OF ULCERATIVE COLITIS

*To the Editor* 'Psychiatric Aspects of Ulcerative Colitis' by Dr George E. Daniels in the January 29 issue of the Journal, is to my mind at variance with clinical experience

The performance of serologic tests for syphilis in a nonroutine manner, as is frequently requested for premarital examinations, is not feasible under the present laboratory setup. The very large number of routine tests (upward of 40,000 in January) throws such a burden on the facilities and personnel of the laboratory that it is not practicable to impose the additional burden of accepting specimens out of turn and testing them by nonroutine methods. Furthermore, it is unfair to accept such specimens at all unless the practice can be made general, and our physical facilities do not permit of expansion to carry such an added burden.

The rendering of reports by telephone, which is also requested frequently, would appear to be barred by the provisions of Section 119 of Chapter 111 of the General Laws, which provides that "... laboratory ... records pertaining to gonorrhea or syphilis shall not be public records, and the contents thereof shall not be divulged by any person having charge of or access to the same, except upon proper judicial order or to a person whose official duties, in the opinion of the commissioner, entitle him to receive information contained therein." As the purpose of this statute is to protect the individual, and as the laboratory has no way to identify the source of telephone calls, it would seem that reports can be sent to physicians only by mail or by a duly accredited messenger.

Authorization to perform premarital examinations was granted to medical officers of the United States Army, Navy and Public Health Service on active duty by Chapter 697 of the Acts of 1941; and all Army, Navy, Public Health Service and state health department laboratories were approved by the Public Health Council for the performance of the necessary serologic tests. It is suggested that physicians call these provisions to the attention of the prospective brides of men in military service, so that the latter will not delay their own examinations needlessly.

In further recognition of the fact that many times the circumstances of military service and so forth give applicants for marriage licenses only a short time in which to fulfill the requirements of the law, we have inquired of all laboratories approved for performing serologic tests for syphilis as to whether they wish to accept such specimens for rapid testing and what their fees are for such services. This information has been tabulated in the hope that it will prove of service to physicians.

The following laboratories will do rapid Hinton tests (and confirmatory tests when needed) for premarital purposes, at the charge indicated:

Boston Dispensary	\$3.00
Boston Health Department (Boston residents, only)	No charge
Brockton Health Department	
Brockton residents	No charge
Nonresidents of Brockton or nonresident physicians	\$3.00
Leary Laboratory, Boston	3.00
Massachusetts General Hospital	3.00
Mercy Hospital, Springfield	2.00
Peter Bent Brigham Hospital, Boston	3.00
Providence Hospital, Holyoke	2.00
St. Luke's Hospital, Pittsfield	1.00

PAUL J. JAKMAUH, M.D.  
*Commissioner of Public Health*

State House  
Boston

## REPORTS OF MEETINGS

### HARVARD MEDICAL SOCIETY

A regular meeting of the Harvard Medical Society was held at the Peter Bent Brigham Hospital on November 12, with Dr. Elliott C. Cutler presiding.

The case presented was that of a seventy-three-year-old man admitted after an alleged injury in an automobile accident. When first seen, the patient appeared to be in shock but was mentally clear, with a blood pressure of 90/60. He was given emergency treatment for shock. Physical examination revealed mobility and crepitus of the pelvic bones, an obvious fracture and tearing of all the ligaments of the right ankle, and a sprain of the right knee; neurologic examination was negative. After an hour, the chart showed that the general condition was good, and the patient was removed to the operating room, where, under Pentothal anesthesia, the fractures were reduced. Again, the blood pressure fell, and he was given intravenous saline solution, 25 gm. of human albumin and a small blood transfusion. Hematocrit readings were taken at the time and subsequently as an aid in following the course of the patient. The later course was essentially smooth except for an anemia, for which he received further transfusions.

In discussing the case, Dr. Carl Walter emphasized the age of the patient, the fractures of the leg and pelvis and the element of shock. The early treatment of the fractures and the shock is an aid toward a favorable outcome, especially in aged patients. In all fractures of the pelvis, the question of bladder injury arises, but there was no evidence of any in this case.

The speaker of the evening was Mr. Gordon Gordon-Taylor, surgeon to Middlesex Hospital, London, and Surgeon Rear Admiral to His Majesty's Navy, whose subject was "Certain Surgical Problems of Modern Warfare." Slides were shown of the building of the Royal College of Surgeons before and after the bombing of May 10 and 11 of this year, when such damage was done that the collection in the Hunterian Museum was reduced from 14,000 to 3800 specimens.

The characteristic feature of the wounds in World War II has been their multiplicity—to an even greater extent than in World War I. Blast wounds have been common, and small fragments of glass or other debris often enter the superficial tissues. The best form of treatment in such cases is to paint the wounds with 1 per cent gentian violet or some other weak antiseptic and allow the foreign bodies to extrude themselves. This usually takes place without complication on about the tenth day.

The great paucity of gas gangrene as compared with 1914-1918 may be attributable either to the use of the sulfonamide group of drugs or to the plaster method of treating compound fractures. The incidence has been less than 1 per cent. The wounds were undoubtedly as well cleaned and débrided in the last war, and gas-bacillus antiserum is being employed only in wounds that involve regions known to predispose to gas infection, such as the buttocks, perineum, calves and inner thighs. This type of infection is certainly not unknown in the Navy, as was formerly taught, but is much less common.

Whether the type of injury is responsible is not certain, but secondary hemorrhage—the bugbear of the base hospital during the last war—is almost unknown. Similarly, traumatic aneurysm has become much rarer.

In wounds of the face and jaws, wide excision of tissue is almost never necessary, for the blood supply is

excellent and gas gangrene is very rare. Immediate surgery is carried out if possible. Dependent drainage in fractures of the jaw is probably the most important single procedure. Whenever possible, the mucous membrane should be sutured immediately.

In the management of burns, there has been a recent trend away from the use of tannic and other eschars, especially on the face and hands, where early motion is a desirable factor. There seems to be little question that an eschar of some sort is necessary to save lives in widespread burns, but there is no unanimity of opinion regarding the face and hands. There are advocates for wet saline dressings, *tulle gras* and certain ointments.

The most frequent injuries sustained in the naval forces are those associated with mine explosions, which usually involve small commercial vessels or mine sweepers. The force is borne in the long axis of the body. Fractures of the os calcis and, to a less extent, the astragalus are most frequently seen. As might be expected, there is a high incidence of fracture of the lumbar spine in these casualties. Also encountered are fractures around the knee of the femur and of the tibia, particularly the so-called "bumper" type.

Injuries to the chest are of the same severity and frequency as those during the last war, but the treatment differs in that the wounds are usually drained for the first two or three days instead of being closed tight and subsequently aspirated. Together with abdominal wounds they are the most infrequently seen, at least in the hospitals, possibly because such a large percentage of these patients die almost immediately. The same general rule holds in naval surgery, namely, that men hit in the trunk invariably die. In abdominal wounds a complete examination is especially necessary, for there is often a very small wound of entry causing considerable internal damage. Wounds of the buttock are particularly prone to involve the peritoneal cavity, and one should always treat them with that possibility in mind. In general if wounds of entrance and exit are found in both rectus muscles, one can be fairly certain that the peritoneal cavity has not been involved. Among patients with peritoneal involvement, the mortality was highest among those under twelve years of age, but the general mortality was also high. However, cases were cited in which patients with profound wounds were saved by the use of prodigious amounts of blood and plasma, and the lesson to be learned is the necessity for large amounts of these lifesaving substances. Abdominal wounds in pregnant women have been almost universally fatal. On the other hand, few cases have been lost in maternity hospitals, even when such hospitals have been demolished, for it is usually possible to evacuate the patients in time. The prolapse of bowel in wounds of the abdomen apparently makes the prognosis much worse. Although one receives the impression that a large percentage of injuries to the bowel are fatal, statistics actually reveal a gross salvage of 40 to 50 per cent. The mortality in prolapse is about 80 per cent. Multiple wounds elsewhere in such patients are far greater in the present war, and the great lifesaving value of the resuscitation officers, with their plasma and blood makes many seemingly moribund patients operable. Abdominothoracic wounds contribute from 10 to 12 per cent of all wounds, as in the last conflict, with essentially the same recovery rate of 66 per cent. Injury to the right side offers a better prognosis for only the liver is involved, contrasted with stomach, spleen and bowel on the left side. The respective mortalities are 50 and 70 per cent.

Blunt injuries more frequently involve the thoracic than the abdominal viscera. This is also borne out by experimental work. Pathologically, multiple small subserous and submucous hemorrhages and tears are found. In naval warfare, this type of injury is sustained by survivors of sunken ships who are swimming in the water as depth charges explode.

## EVANS MEMORIAL HOSPITAL

At a meeting at the Evans Memorial Hospital on November 21, Dr. Alvah H. Gordon, emeritus professor of medicine at McGill University, Montreal, spoke on Bone Changes in Certain Medical Diseases. He emphasized the fact that bone has now become a recognized tissue with an active metabolism rather than merely a static structure with morphology. The discussion consisted of a lantern slide demonstration of certain bone changes, common and rare, seen during a long experience.

Examples were shown of typical cases of certain metabolic diseases, such as gout, rickets, scurvy and lead poisoning. The fuzzy epiphyseal line in rickets was contrasted with the sharpness of that in scurvy, and the two were differentiated from congenital syphilis, which so often occurs in the same age group. Also briefly discussed were the changes of hyperparathyroidism.

The next group concerned hormonal imbalances. In the hyperpituitarism of Simmonds's disease, a characteristic widening of the sella turcica offers presumptive evidence of the diagnosis. A case of renal rickets, which was diagnosed at autopsy and was seen by many authorities during life, was considered a case of hypopituitarism. The relatively new concept that a postmenopausal osteoporosis is caused by lack of estrogens rather than by an inadequate diet has resulted from the work of Albright. Paget's disease, characterized by both an increase of growth and a degeneration of bone, is often found more or less accidentally or as the result of a pathologic fracture. The latter are usually transverse. Multiple myeloma can usually be found in several bones and clinically is on the borderline of malignancy. The unusual character of the bone metastases in carcinoma of the prostate and breast, which are oftener productive than destructive, was pointed out. Leukemia and leukemoid states frequently reveal bone changes, and these may also be osteosclerotic in leukemic leukemia. There is an enlarged spleen, frequent backache and an elevation of the myelocyte count to high levels. An unusual case was cited in which such a process practically displaced all the active bone marrow, the spleen was enormously hypertrophied in an attempt to compensate for this displacement. Hand-Schüller-Christian's disease was mentioned in passing.

Finally, Dr. Gordon discussed achondroplasia, in which the short body is surpassed by even shorter arms. The mentality is rather good and is a definite point of differentiation of cretins and achondroplastics. Such people are invariably strong for their size. They should be classed as clever rather than intelligent, however.

## BOOK REVIEWS

*Arthritis and Allied Conditions*. By Bernard I. Comroe, M.D. Second edition, thoroughly revised. 8", cloth, 878 pp., with 242 illustrations. Philadelphia: Lea and Febiger, 1941. \$9.00.

In the second edition of this book, a number of additions have been made to keep pace with the ever-expanding

knowledge of this group of diseases. A number of faults in the first edition have been corrected. The text is more carefully written, and the descriptions are clearer. There is logical arrangement of the material. The illustrations are excellent. Unfortunately, most of them have been borrowed from publications by other men. It would add to the value of the book if there were more sketches or photographs of necessary apparatus and braces, since many of these illustrations give no clear idea of the form of the apparatus or how it should be fitted. The book is complete, as full a presentation of knowledge as is possible. In the opinion of the reviewer, the weakest chapters are those dealing with related orthopedic lesions, in which the author's experience is necessarily limited; these could be omitted without lessening the value of the book. A well-selected bibliography follows each chapter.

Although this is an excellent discussion of arthritis, probably the best yet to appear in the English language, the average reader will be dismayed by its voluminousness. In an attempt to cover completely all diseases in which there is disability in the joints, the size of the book has become rather too large to attract a busy general practitioner. Those interested in treatment of chronic arthritis will find here an up-to-date summary of physiologic, pathologic and therapeutic data. Controversial subjects are presented without bias. But the author, mature in experience, has not hesitated to state his own opinion about them. This book should be welcomed by the physician who has the time and patience to read so large a volume, and it should be particularly helpful to those who treat chronic arthritis.

---

*Stethoscopic Heart Records: Sounds, murmurs and arrhythmias.* By George D. Geckeler, M.D. Columbia Records, Set M-600. Seven records. Price \$12.75.

The faithful reproduction of heart sounds and murmurs by means of phonographic records is a feat that has tantalized and baffled sound engineers for nearly twenty years. The problems involved are extremely complex, and although this collection indicates that progress is being made, it also shows that there is still room for improvement. The technic of heart-sound reproduction involves the screening out of certain frequencies, to exaggerate other sounds that it is desired to bring out. The accomplishment of such selective exaggeration without undesirable distortion has seldom been achieved. In Dr. Geckeler's series, a good reproduction has been accomplished in about half the recordings. The most unsatisfactory are the attempts to reproduce gallop rhythm and faint mid-diastolic murmurs. The common arrhythmias, the aortic systolic and diastolic murmurs and the louder mitral diastolic murmurs are well illustrated. The best recordings are so very good that one can only hope that Dr. Geckeler will eventually succeed in bringing them all up to the same high standard. As they are, they should prove helpful in teaching auscultation to beginners.

---

*Development Diagnosis: Normal and abnormal child development; clinical methods and practical applications.* By Arnold Gesell, M.D., and Catherine S. Amatruda, M.D. 8°, cloth, 447 pp., with 20 illustrations. New York: Paul B. Hoeber, Incorporated, 1941. \$6.50.

This is an elaborate experimental research on the development of behavior in infants from the time of birth up to the second year of life. The first part of the volume

details what a child should be able to do, if it is both mentally and physically normal, at the age of four, sixteen, twenty-eight and forty weeks and twelve, eighteen, twenty-four and thirty-six months. The methods of examination are given in great detail, with proper illustrations. This part of the book should be of value to all pediatricians in quickly estimating the capacity of a child.

The second part deals with various abnormal states: amentia, endocrine disorders, convulsive and other neurologic states, cerebral injury, prematurity, precocity and environmental retardation. This section of the work is not so elaborate as the first section, but is valuable in a general way. Other clinics, with larger experience, could use the material here presented as a basis for more extensive investigations. The most important chapter, on the clinical aspects of child adoption, is full of sound advice regarding this subject from the authors, who have had extensive experience.

A further section of the book deals with diagnosis, guidance and development supervision.

In general, this work is a fundamental text from a clinic of worldwide reputation. No other recommendation is needed.

---

*Brucellosis (Undulant Fever), Clinical and Subclinical.* By Harold J. Harris, M.D. Foreword by Walter M. Simpson, M.D. 8°, cloth, 286 pp., with 12 colored and 44 black-and-white illustrations. New York: Paul B. Hoeber, Incorporated, 1941. \$5.50.

This monograph covers the history of brucellosis, as well as its etiology, epidemiology, pathology, symptomatology, diagnosis, prognosis, treatment and prophylaxis. Dr. Harris has had an active practice of medicine in a rural area and has based much of his work on the personal observations made on 250 patients with the disease. It is his opinion that infection with the disease is far greater than has generally been supposed, and that the chronic form constitutes 90 to 95 per cent of all brucellar infections. He states that this disease ranks with tuberculosis, syphilis and pneumonia in incidence, although not in mortality. He compares the disease to syphilis, because of its protean manifestations.

The major part of the book is devoted to symptomatology and diagnosis. There are colored illustrations of skin lesions and positive skin tests. Of particular interest to the practitioner is the composite picture of the most usual complaints encountered in the disease. Although farmers, dairymen and slaughterhouse workers contract the disease by direct contact, the greater part of the incidence is due to raw dairy products. The summer tourist may easily pick up the infection even though the greater part of his year is spent in areas where pasteurization is prevalent. Dr. Harris advocates the pasteurization of all milk and the destruction of all infected cattle, sheep, goats, pigs, horses and other domestic animals known to harbor the disease. Such a destruction would require a large expenditure of money, since it is estimated from surveys that between 11 and 20 per cent of all the cows in the United States are infected, and 20 per cent of the hogs in Iowa. Complete pasteurization seems possible, but at the present time, some communities and even entire states are so blind to the menace of raw milk that pasteurization is neglected.

This volume should be of great help to practitioners in communities where raw milk is consumed, and it would be a valuable addition to any physician's library.

## PRESENTATION OF THE HENRY JACOB BIGELOW MEDAL

### INTRODUCTORY REMARKS\*

IRVING J. WALKER, M.D.

BOSTON

THE occasion of this joint meeting of the Boston Surgical Society and the American College of Surgeons is for the presentation of the Henry Jacob Bigelow Medal to one chosen by the Boston Surgical Society for outstanding contribution to the advance of surgery.

As president of the Boston Surgical Society, it seems fitting that I should remind you of something of the life of Henry Jacob Bigelow, in whose honor the award is made, as well as of the history of the Bigelow Medal.

Dr. Bigelow was born in Boston in 1818, the son of a physician who was a professor in the Harvard Medical School. His preliminary education was received in Boston schools. He graduated from Harvard College in 1837, and from the Harvard Medical School in 1841. In 1846, he was appointed surgeon to the Massachusetts General Hospital, in which capacity he functioned for the next forty years. From 1849 to 1882, he was professor of surgery at Harvard Medical School. Harvard University awarded him the honorary degree of LL.D. in 1882. He died in 1890, at the age of seventy-two.

\*This and the two following articles comprise the addresses made at the presentation of the Henry Jacob Bigelow Medal at a combined meeting of the Boston Surgical Society and the American College of Surgeons at Boston, November 7, 1941.

Much has been written of the life of Henry Jacob Bigelow. One might summarize by stating that he was a most dynamic personality of the inventive and investigative type of mind, and a clear and practical instructor of students. One of his contemporaries said, "To see him operate is to recognize a master." Dr. Bigelow contributed much to the advance of surgery.

In 1915, his son, Dr. William Sturgis Bigelow, in memory of his father, gave to the Boston Surgical Society a sum of money, the income of which was to be used from time to time for the presentation of a gold medal, to be called the Henry Jacob Bigelow Medal, for new and valuable work in surgery or connected with surgery. That the Boston Surgical Society has guarded this trust is evidenced by the names of the following internationally recognized surgeons who have received the award: William J. Mayo, William W. Keen, Rudolph Matas, Chevalier Jackson, George Grey-Turner, John M. T. Finney, Harvey Cushing and Edward W. Archibald.

Tonight, we meet to honor one who needs no introduction to the medical profession, a modest and respected gentleman, a profound student of surgical problems, an inspiring and stimulating teacher, an accomplished surgeon. I have the honor of presenting to you Dr. Allen Oldfather Whipple.

## PRESENTATION OF THE MEDAL

DAVID CHEEVER, M.D.

BOSTON

DR. WHIPPLE, having voted to confer on you the Bigelow Medal, the Boston Surgical Society has delegated to me the honor of presenting it to you. We, the members of the society, and others of your friends here assembled, including many fellows of the American College of Surgeons who are in attendance at their annual clinical congress, need no enlightenment about the reasons for this award, but citizens in other walks of life will wish to know the grounds for the bestowal of so signal an honor—an honor paid to but eight other recipients in the twenty-six years since the medal was established. A brief citation of these grounds is therefore appropriate.

Born in Persia, where you spent the formative years of childhood and boyhood, you were nevertheless not imbued with the fatalistic and mystical philosophies of the Orient but found rather the master key to life's problems in the principles of free will and self-determination bequeathed to you from seven generations of your New England ancestors. At Princeton, you received your cultural and basic scientific education, and it is an interesting example of the shrewd intuition of youth that your classmates voted you the man most likely to succeed in afterlife. Your medical degree was won from the College of Physicians and Surgeons of Columbia University, and there followed internships at the Roosevelt Hospital and the Sloane Maternity Hospital. You then entered the service of the Presbyterian Hospital as surgeon and pathologist, passing rapidly up the steps of surgical preferment until, in 1921, but thirteen years after graduation in medicine, you were appointed professor of surgery in your alma mater and director of the Surgical Service of the Presbyterian Hospital. Your post bears the name of the illustrious Valentine Mott, who, a century ago, was your predecessor as professor of surgery and as the leading surgeon in the greatest city of America.

The qualities you have displayed in this high post and the things you have accomplished must be touched on, although at the certain risk of offending your modest self-appraisal. As a surgeon, you have ever advanced the science and perfected the art; nothing in the whole field has

been alien to your interest, and to whatever special problem you have addressed yourself you have brought clarification. Whatever tissue or organ is to be the object of your beneficent attention, your procedures are based on thorough knowledge of its anatomy, its physiology and its pathology. The diseases of the upper abdomen have constituted one of your special interests. You have demonstrated convincingly the possibility of the successful extirpation of the duodenum and head of the pancreas for carcinoma; your success in the diagnosis and removal of pancreatic tumors for the cure of that distressing and fatal malady, hyperinsulism, makes you the foremost authority in that field; on the physiology and pathology of the spleen,—described by Galen as an "organ full of mystery,"—you have thrown light that has helped to establish a rational approach to surgical therapeutics. Indeed, your most recent research has, by ingenious methods, perhaps definitively settled the old problem of the nature of the circulation in the spleen and portal bed. Your common sense has told you that profundity of knowledge alone on the surgeon's part will not ensure a successful operation, that the successful technical application of that knowledge to human tissues is of equal value; therefore, you have found not unworthy of intensive study the everyday problems of suture and ligature material and of wound healing.

For twenty years, you have directed the Surgical Service of the Presbyterian Hospital, and the teaching of surgery in the College of Physicians and Surgeons. This has been a period of change in plant, in organization, in methods, in social outlook, when failure might have attended the administration of one who had not your courage, your gentleness, your practical idealism, your fairness and, above all, your intellectual integrity. You might have inspired the ancient aphorism: *Fortiter in re, suaviter in modo*. Doubtless, you have found your greatest satisfaction in the relief of human ills, but scarcely less has been your happiness in the education of young men—you are a crusader for better training in surgery, in both undergraduate and postgraduate years. Distinguished as a clinician, you have been led by your investigative point of view beyond the clinic

to fruitful study in the laboratory. In inspiring research, you have been a veritable catalyst—although perhaps the analogy is not a sound one, since the catalyst, in achieving its reactions, does not expend itself.

A full curriculum *vitae vestrae* should list the hundred titles from your pen under which you have shared your knowledge with your colleagues, should enumerate the societies in which you hold membership and high office, should report your honors, and should speak of your unselfish work in helping to create and support high standards of surgical work. It should mention the talents in

music, in painting, the interest in books and in history, which add to your Spartan qualities of courage and self-discipline attributes more Attic in their nature. It may only hint at tender personal relationships, which, through the years, have supported you by your hearthstone.

Among your avocations, I am told, is numismatics. Here, then, is a medal to be added to your collection, beautifully wrought in purest gold. It is indeed a jewel to be treasured, but it is our happy belief that it will chiefly signify to you an enduring token of the confidence and affection of fellow workers in the field of surgery.

## PRESENT-DAY SURGERY OF THE PANCREAS\*

ALLEN O. WHIPPLE, M.D.†

NEW YORK CITY

Much harm has been done in Medicine by the partial representations of those who, having a point to prove, have suppressed their unsuccessful experiments and brought into view none but favorable facts.

From the preface to *American Medical Botany*, by Doctor Jacob Bigelow, published in 1820.

**K**NOWLEDGE of the pancreas, its anatomy, physiology, pathology, symptomatology and therapy is of comparatively recent date. Less than a hundred years ago, this organ was spoken of as the abdominal salivary gland. The German term *Bauchspeicheldrüse* still connotes that meaning. Bernard,<sup>1</sup> in 1856, was the first sound contributor to the physiology of this organ in his experimental studies of the action of pancreatic juice in food digestion. Langerhans,<sup>2</sup> while still a medical student in Berlin, published his remarkable histologic studies of the pancreas as his inaugural dissertation in 1869. Using the transillumination method, as Lister<sup>3</sup> did in his study of inflammation, a method only recently revived so effectively by Knisely,<sup>4</sup> Langerhans described the several types of cells and tissues in the pancreas and by his own original methods of dye injections showed the acinar tissue to be separate from the islet tissue. These collections of cells, which he termed "our cells," were given scant notice until the French histologist, Laguesse,<sup>5</sup> recognized their anatomic importance and in 1896 called them *les îlots de Langerhans*, and Langerhans cells they have since been called.

The persistence of these islands, with atrophy

of the acinar tissue, after ligation of the pancreatic ducts, had led many observers to consider islet tissue as directly related to an internal secretion that controlled sugar metabolism. In 1889, a most significant year in the story of the pancreas, von Mering and Minkowski<sup>6</sup> for the first time demonstrated the exact role of the organ in carbohydrate metabolism and in diabetes mellitus by their experimental studies in pancreatectomized animals.

Several investigators, during the next thirty years, were on the very verge of isolating the internal secretion of islet tissue, and in more than one case made an extract to be injected into pancreatectomized animals with diabetes, but because of impurities or insufficient amounts did not accomplish the crucial result. It remained for Banting and Best<sup>7</sup> to demonstrate to a waiting world, by positive and conclusive experimental physiology, this internal secretion, since named insulin, and to apply it therapeutically in the treatment of diabetes. Their announcement of this epoch-making discovery was published in 1922.

A rapidly developing knowledge of blood chemistry as the chief aid in the study of metabolic disease was of the greatest help in the immediate acceptance of insulin therapy. But it soon became evident that overdosage caused a sharp drop in blood sugar, giving rise to the protean manifestations of so-called "insulin shock," and the avoidance and treatment of this syndrome became a major problem. During this period of four or five years after the discovery of insulin and its therapeutic complication, the idea occurred to Harris,<sup>8</sup> of Birmingham, Alabama, that overactive islet tissue, either as hyperplastic islands or as tumors of islet tissue, might account for the clinical

\*From the Department of Surgery, Columbia University College of Physicians and Surgeons.

†Valentine Mott Professor of Surgery, Columbia University College of Physicians and Surgeons, director, Surgical Service, Presbyterian Hospital.

picture of central-nervous-system disturbances associated with hypoglycemia. He discussed this possibility with Banting, who agreed with him in his hypothesis. Several years later, a physician, suffering with the syndrome of severe insulin shock in the fasting state, went to Rochester, Minnesota, and after consultation with Wilder<sup>9</sup> and William J. Mayo, the patient was operated on by Dr. Mayo, who found a tumor of the pancreas with metastases to the liver. The tissue removed at operation proved to be an islet-cell tumor. Several weeks later, autopsy corroborated the diagnosis, and biologic assay of the liver metastases showed large amounts of insulin in the tumor tissue.

In 1929, Graham,<sup>10</sup> of Toronto, removed a benign adenoma of islet tissue from a patient who was immediately relieved of her symptoms of hyperinsulinism, and has remained cured to date. This initiated a new and the latest phase of endocrine surgery, a type of surgery requiring the skill in diagnosis and operative technic previously demonstrated in the removal of tumors or hyperplasias of the thyroid, pituitary, adrenal and parathyroid glands.

The relation of islet tissue to hypoglycemic states had been noted in 1926, when Gray and Feemster<sup>11</sup> reported the finding of hyperplasia of islet tissue in an infant who was born of a diabetic mother and died in convulsions shortly after birth. The fetus had been supplying the diabetic mother with insulin, and with the sudden cessation of the physiologic demand at birth, the hyperplastic islands caused low blood sugar and insulin shock in the infant.

Clinical tests of the external secreting function of the pancreas, although still in the experimental phase and not as yet completely satisfactory, are contributing materially to the diagnosis of the acute and chronic lesions of this organ. These newer methods have replaced the older tests of the stools for pancreatic digestion. These may be divided into those useful in the differential diagnosis of the acute lesions and those in the chronic inflammatory and obstructive lesions.

Tests for the acute lesions consist of lipase and amylase determinations in the blood serum. During the early stages and for the first three or four days after the onset of acute pancreatitis, the edema of the gland shuts off the ducts, and both the obstructed lipase and amylase pass into the blood stream, giving high levels of these proenzymes in the blood. It must be emphasized that this concentration of lipase and amylase for diagnostic purposes takes place only in the first four or five days after the onset of the acute lesions. These determinations, moreover, do not differentiate the type of acute pancreatitis or the severity of the

process. Observations of these elevated serum lipase and amylase levels have been made in a number of clinics. Comfort and Osterberg,<sup>12</sup> of the Mayo Clinic, reported a series of acute pancreatic lesions, proved by the surgeon or pathologist, as follows: elevated values for serum lipase were obtained in 31 of 32 cases, and elevated values in serum amylase in 7 out of 10 cases. At the Presbyterian Hospital, using serum amylase readings, we have found elevations of 50 to 300 per cent in 44 of 60 cases. Of the 14 cases that did not show an elevation, 5 had a history of onset of the acute symptoms ten days to five weeks before the test was made, so that one may say that serum amylase determinations were significant in 80 per cent of 55 patients. We use the rather simple Myers<sup>13</sup> starch-digestion test because it is easily done, gives the result within an hour, and can be made in any laboratory by a well-trained technician, resident or intern.

The tests for determining the chronic inflammatory lesions and the chronic obstructive lesions of the pancreas are based on the work of Swedish investigators. Starling,<sup>14</sup> in 1907, reported the discovery of secretin in the succus entericus. But it was not until 1937 that Agren and Hammersten<sup>15</sup> isolated the hormone, secretin, in crystalline form. Injected intravenously, this hormone causes a great increase in the flow of pancreatic juice. Lagerlöf,<sup>16</sup> using the two-tube intubation technic, with one tube in the stomach and the other in the duodenum, was able to aspirate pure pancreatic juice in large amounts by injecting secretin intravenously in normal controls. In chronic inflammatory or sclerosing lesions of the pancreas, the response to secretin is markedly diminished. In obstructive lesions of the papilla of Vater or of the head of the pancreas, the flow is absent and differentiates these lesions from the jaundiced patients with carcinoma of the common or hepatic ducts.

More recently, the use of Mecholyl or methylacetylcholine has further elaborated the duodenal determinations of pancreatic ferments. Secretin, which is a hormone, increases the volume and alkalinity of pancreatic juice. Mecholyl, acting through the vagus, increases the concentration of the ferment without increasing the volume and alkalinity, and is a more accurate index of the activity of the acinar tissue than of the obstruction of the flow of the pancreatic juice.

Contributions to the knowledge of the pathology of the pancreas have been made chiefly by Americans. Although autopsy findings in acute pancreatic lesions had been described by Schmackpfeffer<sup>17</sup> in 1817, Clässen<sup>18</sup> in 1842, Friedreich<sup>19</sup> in 1875 and Balser<sup>20</sup> in 1882, it remained for Fitz,<sup>21</sup> the distinguished physician and pathologist of Bos-

ton, to present the first clear-cut correlation between the acute hemorrhagic and acute suppurative lesions of the pancreas and the clinical picture; he deserves full credit for calling the attention of physicians and surgeons to the entity of acute pancreatitis. It was in 1889 that Fitz delivered his famous Middleton-Goldsmith Lecture before the New York Pathological Society.

More recently, a new chapter in the pathology of the pancreas has been added by pathologists and clinicians of this continent in their studies of islet-cell tumors. These tumors were practically unknown until their clinical significance was recognized.

In 1926, Warren,<sup>22</sup> of Boston, was able to collect only 20 cases of islet adenoma, 4 of them his own, from the entire literature. At that time, no clinical significance was attached to these growths. With the removal of the carcinomatous islet tissue in 1927 by Dr. Mayo and the islet adenoma in 1929 by Dr. Graham, interest in this remarkable endocrine tumor increased rapidly. Since then, over 100 patients have been operated on, and most of these tumors have been found by surgeons at operation; this is rather a sad commentary on the care with which the pancreas is usually sectioned and examined on the autopsy table. These adenomas are, of course, small, averaging not more than a centimeter in diameter, but they should be found more easily by the pathologist than by the surgeon. The pathology of the tumors and the difficulty of grading them have been carefully studied in our laboratory and reported by Frantz.<sup>23</sup>

This review of the contributions to knowledge of the pancreas is given because of its bearing on present-day ideas of therapy. During the past five to ten years, surgeons have become more conservative in the treatment of the inflammatory lesions and more radical in the surgery of the tumors of the pancreas, and this attitude is the result of the increasing knowledge of the physiology and pathology of this organ, the additions to the diagnostic armamentarium of clinical tests, and the means of combating jaundice and shock in operations for cancer of this gland.

#### ACUTE PANCREATITIS

This lesion as now accepted may vary from an acute edema to a complete necrosis of the entire organ. The pathogenesis of the several varieties of acute pancreatitis is still undetermined. It is definitely established that factors of trauma, vascular injury, infection and bile invasion or bile reflux can initiate and continue the process of acute inflammation. It is probable that the toxic effect of the lesions showing acute hemorrhage and acute necrosis, and evidenced by shock and collapse, may be associated with any of the above inciting

factors, and that it is probably the result of decomposition of proteins or protein-split products by bacteria or their proteolytic enzymes. The exact nature of the poison or poisons causing the shock and collapse remains speculative. The fact that in the majority of these acute lesions there is associated biliary-tract disease points to a close relation of bile invasion as the commonest factor in the pathogenesis, and favors the "common-channel" theory.

Until recently, it was generally accepted that bile or duodenal contents, as an inciting factor, activated the proenzyme, trypsinogen, converting it into trypsin, and that by its action, autodigestion of the parenchyma of the pancreas took place. This idea seemed to be borne out by the experiments of Guleke<sup>24</sup> and Pólya<sup>25</sup> in Germany, and of Sweet<sup>26</sup> in this country. It should be pointed out that the pancreatic tissues they worked with were not sterile. More recently, however, very carefully checked experiments by Dragstedt and his associates,<sup>27</sup> at the University of Chicago, have cast great doubt on the theory of autodigestion, and point convincingly to the evidence that the acute pancreatic lesions, commonly associated with bile invasion of the ducts, are the result of the destructive action of bile salts and that the bacteria in the ducts and pancreatic tissue, especially the anaerobes growing in the damaged or necrotic tissue, increase the damage and give the toxic symptoms. Dragstedt's discussion deserves the most careful attention of every student of this subject.

In the clinical picture of these severe lesions, shock is the most serious phase of the symptoms and signs. In the milder form of edema of the pancreas, shock is usually not evident, but in the hemorrhagic and necrotic varieties shock is so serious that it is the only condition that should be treated at first. It is manifested by great hemoco-concentration, low blood pressure, rapid pulse and vasomotor atony. It should be treated by plasma transfusion, physiologic saline solution and adrenocortical extract. If surgery is resorted to before the shock is relieved, the mortality will be as high as it has always been—around 50 per cent.

Inasmuch as the same symptom picture is seen in other acute upper abdominal lesions,—especially in high-strangulation ileus and perforated ulcer, in which operative delay is so hazardous,—the differential diagnosis of acute pancreatitis is most essential. It is in these conditions that serum amylase and lipase readings are of the greatest help, as are three-position films of the abdomen to determine fluid levels in the small intestine in ileus and in subphrenic and subhepatic areas in perforation of the gastrointestinal tract. If serum amylase readings are definitely elevated and fluid

levels and free air are ruled out by x-ray examination, the diagnosis of acute pancreatitis can be safely made, the patient can be treated for shock, and surgery can be delayed. Many of these patients, the majority in fact, show such marked improvement in six to twelve hours that surgery can be postponed for associated biliary lesions or for localizing pancreatic inflammation or abscess formation. There is no doubt that this conservative policy, now followed in a number of surgical clinics in various parts of the country, has lowered the mortality of acute pancreatitis. In our experience in the past five years, the mortality has been 15 per cent in 46 cases of acute pancreatitis of various grades, as proved by delayed operation or by autopsy. In the two previous five-year periods, when operation was done as soon as the diagnosis was made, the mortality had been 35 per cent.

We prefer the serum lipase to the amylase test. We use the Myers<sup>13</sup> test, which employs the serum in graded dilutions of starch, to determine the amylase action.\* This test can be done within an hour and by any of the laboratory technicians, residents or interns trained in its use.

#### CHRONIC PANCREATITIS

The surgery in these lesions, vague and uncertain as they are to diagnose clinically, has not made any definite advances. In the cases associated with jaundice, short-circuiting operations, like cholecystoduodenostomy and cholecystojejunostomy, but preferably choledochoduodenostomy, are indicated for two reasons: to relieve the intolerable itching, and to improve fat digestion. Diagnostic tests of pancreatic secretion, using a duodenal tube and secretin and Mecholyl intravenously, are of value in differentiating chronic pancreatitis and cancer of the pancreatic head with complete duct obstruction.

#### CYSTS OF PANCREAS

The differential diagnosis of pancreatic cysts will always be a fascinating problem in abdominal masses. A recent history of upper abdominal crisis

\**Method:* To one tube (A), add 2 cc. blood (or serum), 7 cc. water and 1 cc. 1 per cent starch solution (freshly boiled and cooled); to another tube (B), add 2 cc. blood (or serum) and 7 cc. water. Mix and incubate both tubes exactly fifteen minutes at 40°C. Chill promptly in ice water, and add about 0.5 gm. picric acid to each tube and 1 cc. of the starch solution to B; filter. To three Folin sugar tubes graduated at 25 cc., add: 3 cc. filtrate from A; 3 cc. filtrate from B; and 3 cc. standard .02 per cent glucose solution saturated with picric acid. To each tube, add 1 cc. 20 per cent sodium carbonate solution; mix; place in boiling water for fifteen minutes; cool; dilute to 25 cc.; and mix. Compare the A and B mixtures with the glucose standard in a colorimeter. The amount of glucose in each is calculated according to the following formula:

$$\frac{\text{Standard reading}}{\text{Unknown reading}} \times 0.06 \times \frac{1}{0.6} = \text{mg. glucose per cc. blood (or serum).}$$

The difference in glucose contents of the two tubes (A and B), expressed in mg. per cc., multiplied by 20 equals the amylase value of the blood (or serum) in Myers and Killian units. One unit of amylase equals milligrams of glucose formed by 20 cc. of blood and 100 mg. of starch in fifteen minutes under experimental conditions. If the value in any sample is higher than 40 units, the test should be repeated, using 1 cc. (or 0.5 cc.) of blood (or serum).

or trauma should always make one think of pancreatic pseudocyst in the presence of a mass in the upper abdomen, especially one to the left of the midline. These so-called "pseudocysts" following trauma or acute pancreatitis develop, as a rule, more rapidly than the retention cysts, the cystadenomatous cysts and the so-called "dermoid cysts" in the pancreatic area. The pseudocysts are unilocular, are usually not lined by epithelium, and when marsupialized or drained are not followed by persistent fistula, as a rule, and therefore give better late results. In the diagnosis of any large pancreatic cyst, a simultaneous barium meal and a barium enema for x-ray studies are of great help in differentiating the lesion from splenomegaly, renal tumor, mesenteric cyst and retroperitoneal masses. A pancreatic cyst pointing forward through the gastrohepatic omentum will push the stomach downward; one pointing through the gastrocolic omentum will push the stomach upward and the colon downward; and one pointing through the mesocolon pushes the colon upward.

Only a small percentage of pancreatic cysts can be completely removed, because of their deep position, their relation to vital structures and their frequent association with large, friable, vascular channels. For this reason, when one explores the abdomen and finds such a cyst, it is imperative to determine by careful inspection, before any attempt is made to excise it, the question of whether or not the cyst is removable; for once the attempt is begun, if it has to be abandoned because of hemorrhage or damage to such vessels as the midcolic, the superior or inferior mesenteric or the portal vein, the mortality rate rises to a high level.

If the cyst is found to be cystadenomatous, multilocular and involving the major portion of the pancreas, it had best be left alone, since marsupialization or drainage will result in a distressing pancreatic fistula. Cystadenomatous cysts in the tail of the pancreas can be removed successfully, but not those in the head and body.

In the unilocular cysts that cannot be excised, marsupialization or drainage should be used. To avoid the skin irritation and the uncomfortable wet dressings from fistulous fluid, continuous suction should be applied through a catheter inside a larger rubber tube placed in the cyst during the postoperative period while the cyst cavity is contracting. After a few days, with decrease of fistulous flow, sclerosing solutions such as those used in the injection treatment of varicose veins frequently diminish the flow of pancreatic juice and within three to four weeks stop it entirely. In

cases in which the fistulous tract persists, it is possible to transplant the tract into the stomach or jejunum. We have marsupialized two large dermoid cysts arising from the region of the body of the pancreas, and at a second operation, in one patient, we were able to excise the remaining fistulous tract, with permanent cure.

### TUMORS OF PANCREAS

A discussion of the surgery of the tumors of the pancreas is a complex subject, surgically simple and agreed to when the growths are benign, but complicated and controversial when they are malignant. Before the discovery of insulin in 1922, which clarified the question of the internal secretion of the pancreas, only a small number of successful removals of benign tumors had been reported. In 1924, Gross and Guleke,<sup>28</sup> in their comprehensive monograph on the diseases of the pancreas, in the section on the treatment of tumors of the pancreas, were able to find only 6 cases of benign tumors removed by operation and reported in the literature. With the report by Wilder and his associates<sup>9</sup> in 1927 of the carcinoma of islet tissue operated on by Dr. Mayo and the paper of Howland et al.<sup>10</sup> describing the first successful removal of an islet-cell adenoma by Dr. Graham in 1929, a new field of endocrine surgery was opened, and since then, in a period of twelve years, over 100 islet-cell tumors have

### Islet-Cell Tumors

The majority of islet cell tumors are microscopically benign adenomas, but a certain number are questionably malignant because of capsule invasion or the finding of islet cells in the blood vessels of the tumors. A minority of such tumors

are obviously malignant, as shown by metastases to the liver or adjacent lymph nodes. A review of the literature and personal communications from surgeons who have kindly sent me reports of their operated cases, as well as our own cases, are referred to in Tables 1 and 2.

It is impossible in this lecture to go into the details of the pathology, symptomatology and treatment of these tumors,<sup>29</sup> but certain points should be emphasized.

Disorders of the liver, adrenal, pituitary and thyroid glands, and thalamus, in which hypoglycemia occurs, must be ruled out.

The syndrome associated with islet-cell tumors must present the following essential triad: attacks of central-nervous-system disorder—motor, vasomotor or psychic—coming on during the fasting state; fasting blood-sugar levels of 50 mg. per 100 cc. or less; and immediate recovery from these attacks on the administration of glucose by mouth or by vein. Unless this triad is present, the diagnosis of a tumor requiring surgery should not be made. In a review of 105 cases of islet-cell tumor removed by operation, only one patient showed a fasting blood sugar above 50 mg. per 100 cc., and his reading was 53 mg. Because we have adhered to this rule, we have found islet-cell tumors at the first operation in 19 of 22 patients, whereas in another clinic, in which the rigid criteria were not followed, tumors were found in only 16 of 46 cases.

In the majority of epileptic and narcoleptic patients with disturbed blood sugar levels, the triad is not found, but in the doubtful cases, electroencephalograms now give tracings charac-

been removed. The pathology, the typical syndrome, the diagnosis and the indications for surgery and the technic of the operation in this group of lesions have now become clarified and standardized, and the results, in qualified hands, are amazingly good

teristic of epilepsy and help to establish the differential diagnosis.

In patients with the definite triad in whom serious hepatic, pituitary, adrenal and thyroid disease has been ruled out, surgery is definitely indicated and should not be delayed, for the following reasons: the continued enormous daily intake of carbohydrate required to prevent hyperinsulin shock results in rapid and marked obesity and makes these patients bad operative risks, and the surgical procedures exceedingly difficult; the repeated attacks of insulin shock or prolonged hypoglycemic states favor subsequent mental instability and deterioration; and the tumors, if questionably malignant while still localized, may metastasize and become inoperable.

In an exploration for these tumors, a thorough search of the mobilized tail, body and head of the pancreas by inspection and palpation must be made, to reveal the tumor or tumors, for more than one may be present. To palpate the head of the pancreas the duodenum must be mobilized to the left, exposing the posterior surface of the head. We have found more than one tumor in 3 cases, and we have removed a tumor from the posterior aspect of the head in 4 patients who had previously been unsuccessfully explored. Five other such secondary operations have been reported, and in 3 autopsies, tumors overlooked at operation have been found.

After such a thorough search has been made and no tumor found, the question of subtotal pancreatectomy must be decided.

Regarding pancreatectomy, mere removal of the tail or less than half the pancreas will not cure the patient. David,<sup>30</sup> of Chicago, has very recently reviewed the indications and results of subtotal pancreatectomy for hypoglycemia. In 22 patients on whom a partial or subtotal resection of the pancreas was done for hypoglycemic attacks, a tumor was found at operation in 18 cases and at a second operation in 4. There were 5 post-operative deaths; 16 of the 17 survivors were cured. It might be said that the tumor should have been discovered at the first operation in all these 22 cases if the organ had been properly immobilized and palpated.

Thirty-five patients, in whom no tumor was found in the excised pancreatic tissue, underwent subtotal pancreatectomy. David divides these cases into two groups. The first group included those in which a partial resection, less than half the organ, was done (18 cases); of these, 15 showed normal pancreas and 3 hyperplasia of islet tissue. Four patients died. Of the 14 survivors, 3 were symptom free, 3 moderately improved, and 8 unimproved. In the second group (17 patients), 35

to 60 gm. of the pancreas was removed, at least two thirds of the organ; of these, 14 showed normal pancreas, 2 hyperplasia, and 1 pancreatitis. One patient succumbed. Of the 16 survivors, 11 were symptom free (7 of these were followed for over two years), 1 was improved, and 4 were unimproved (2 of these had fasting blood-sugar values of 65 to 70 mg. per 100 cc. before operation).

Thus, it is evident that the patients with excised tumors gave far better results than the partially pancreatectomized cases and that the patients in whom no tumor was found gave about 60 per cent cures if 40 to 60 gm. of pancreatic tissue was removed.

In the study of these islet-cell tumors, certain incongruities are notable. The size of the tumor has no relation to the severity of symptoms. The largest tumor in our series gave no symptoms of hyperinsulinism and did not suggest the islet-tumor syndrome. Brunschwig's<sup>31</sup> patient, who had the largest tumor on record (15 by 13 by 10 cm.), did not have lower fasting blood-sugar values or more severe symptoms than many of those with tumors 1 or 2 cm. in diameter. A patient may have a severe convulsion one day, with a fasting blood-sugar level of 45 mg. per 100 cc., and only slight confusion or disorientation the next day, with a reading of 30 or 25 mg. per 100 cc.

The blood-sugar level after a fast of twelve to fifteen hours is a far more reliable test of islet-cell function than the glucose-tolerance curve. We have come to consider the latter entirely unreliable as a differential test, and regard it as a liver-function rather than a pancreatic-function test.

The role of the other organs of internal secretion in the hypoglycemic state of islet-cell tumors is not understood and offers room for much speculation. Without doubt, the pituitary, adrenal and thyroid glands play a more important part than any of the other endocrine organs in exerting some contrainsular or regulating mechanism by secretions opposing the activity of islet tissue. The thyroid gland may be overactive in some of these cases of islet tumor, and with the removal of the tumor, a fatal thyroid storm or crisis may occur. We have had 1 death—1 of the 2 deaths in our cases of benign adenoma—from this cause, and 3 similar cases have been reported.

In every suspected islet-tumor case, the basal metabolic rate should be determined, and if it is at all elevated,—that is, with any reading 'over +15 per cent,—operation should be delayed until the patient has been given a course of Lugol's solution, as in a case of toxic goiter.

We have made tissue cultures from 12 of the 19 tumors that we have removed. The tumor cells

grow readily as epithelial sheets—as well as the connective tissue cells of the stroma. Early in our work, the idea occurred to us of transplanting the tumor cells, which had been grown in the plasma of a diabetic patient, into the areolar tissue of the axilla or groin of this patient. We have tried such transplantations in 4 severe cases of diabetes, with the hope and rationale that the physiologic demand of the patient, on cessation or reduction of insulin, would stimulate the islet cells to grow and supply insulin. In none of the patients so treated, however, was there any evidence of growth or of decreased insulin requirement.

### *Malignant Tumors*

Unfortunately, the surgery of the malignant acinar growths of the pancreas and its closely related ampullary region, involving the common bile duct and duodenum as well as the papilla of Vater and the pancreas, is quite another problem. In cancers of this area,—because of pain and indigestion common to so many upper abdominal functional and organic disturbances and jaundice common to both liver and extrabiliary lesions,—the diagnosis is usually so long delayed that when, as a last resort, these patients are turned over to the surgeon by the diagnostically minded internist, operation reveals a cancer irremovable because of infiltration of adjacent structures or diffuse metastases to the lymph nodes and liver.

A discussion of the surgery of these malignant growths, both past and present, requires a very open mind in evaluating the cruses for the slow progress attained and the advantages and disadvantages of the methods and techniques that during the last five or six years have been developing comparatively rapidly in the radical surgery of these lesions.

The idea of a wide removal of cancers of the ampullary area and pancreatic head was first elaborately described by Desjardins<sup>32</sup> in 1907, and independently by Sauvage<sup>33</sup> in 1908. Both investigators advocated a duodenopancreatectomy. Desjardins advised a one stage operation, which included a gastroenterostomy, a cholecystenterostomy and an implantation of the pancreatic stump into the distal end of the severed duodenum. Sauvage recommended a two-stage procedure, with a gastroenterostomy in the first stage, and a duodenopancreatectomy, with exteriorization of the pancreatic stump to the skin, in the second stage. Neither one of these surgeons carried out his operation in human subjects. The magnitude of the operation in a depleted patient, as well as the bleeding tendency associated with deep jaundice, deterred all but the most ruthless surgeons from attempting such a procedure. Kausch,<sup>34</sup> in 1912, published a report of the first successful opera-

tion with duodenopancreatectomy for carcinoma of the ampulla. He performed the operation in two stages: at first, a cholecystenterostomy and ligation of the common duct and, later, with relief of jaundice, a gastroenterostomy, closing the pylorus, and, after removal of the duodenum and head of the pancreas, suturing of the lower end of the duodenum over the pancreatic stump, which preserved the flow of pancreatic juice into the intestine; the patient lived for nine months but died of an ascending cholangitis. This deep seated conviction that the flow of pancreatic juice into the intestinal tract must be maintained was one of the factors that made the mortality of the operation prohibitive for the next thirty years. Another factor, and one that explained the high incidence of hemorrhage, peritonitis and duodenal and pancreatic fistula in these procedures, whether radical or by transduodenal removal of ampullary cancers was the universal use of absorbible catgut suture and ligature material in these operations. The activated trypsinogen digested the catgut so rapidly that hemorrhage and leakage were almost inevitable. Surgeons dreaded using nonabsorbible material such as silk or linen because of the contaminated field. As a result of the hazard of the radical operation, from 1899, when Halsted<sup>35</sup> reported the first successful removal of an ampullary cancer, to 1935, the transduodenal route was, with few exceptions, the method used in the 76 cases collected from the literature and reported by Hunt and Budd<sup>6</sup> in 1935.

Following a fatal outcome, which was due to a duodenal fistula and peritonitis, in a transduodenal excision of an ampullary carcinoma that I performed in 1935, we decided to undertake a more radical operation in two stages for the following reasons: patients with ampullary cancer were able to survive for months deprived of both biliary and pancreatic drainage into the intestinal tract, and showed an atrophy of disuse of the acinar tissue of the pancreas, if bile could be restored by a short-circuiting procedure, the bleeding tendency would be corrected and digestion of fat improved; and in a later, second-stage operation, radical removal of the duodenum and head of the pancreas, wide of the growth, could be undertaken.

Dragstedt,<sup>37</sup> in 1918, was the first to demonstrate that animals could survive after a complete duodenectomy, and Mann and Kawamura,<sup>38</sup> in 1922, corroborated this observation. It was known that in some cases, as in Kausch's case, duodenopancreatectomy had been done, but without exclusion of the pancreatic juice from the intestinal tract.

In 1935, I assisted Dr. William Barclay Parsons, Jr., in operating on the first patient for whom the two stage procedure was employed.<sup>13</sup> In the second

stage of the operation, a partial duodenectomy and excision of part of the head of the pancreas, with duodenoduodenostomy but with exclusion of the pancreas from the intestinal tract, were ac-

FIGURE 1. First Stage: Cholecystgastrostomy and gastroenterostomy, with ligation of the common duct.

complished. The patient developed a duodenal stenosis requiring a later gastroenterostomy. In the second case in the same year, I performed a

Retroperitoneal  
Area to be drained.

FIGURE 2. Second Stage: Ligation of the gastroduodenal artery and duodenectomy, with removal of part or all of the head of the pancreas.

total duodenectomy, with excision of part of the head of the pancreas, a cholecystgastrostomy and gastroenterostomy having been done in the first stage (Figs. 1 and 2). This patient lived twenty-

eight months, but succumbed to liver metastases. Both patients digested 80 to 85 per cent of a measured fat intake on more than one determination several months after the operation. But both developed cholangitis.

Because of the tendency for infectious material to be forced into the gall bladder by the vigorous contractions of the stomach and a tendency to stenosis of the cholecystgastrostomy opening, with biliary stasis and infection, we<sup>40</sup> modified the short

FIGURE 3. First Stage: Cholecystjejunostomy and end-to-side jejunojejunostomy, with or without a gastroenterostomy.

circuiting procedure in the first stage to an end-to-end cholecystjejunostomy with end-to-side jejunojejunostomy on the Roux principle (Figs. 3 and 4). In 34 cases, the majority of them palliative procedures, we have found a very low incidence of cholangitis and advise it rather than a cholecystgastrostomy.

Now that bleeding in jaundiced patients can be prevented with vitamin K and bile salts, liver damage can be repaired by vitamin B and a high-protein and high-carbohydrate diet, and shock can be averted by continuous spinal anesthesia and whole-blood plasma and serum transfusions, it is possible in early and selected cases to carry out these radical operations safely in one stage. This avoids the hazard of two anesthetics and two major procedures with the handicap of the adhesions following the first stage. We performed the first successful one-stage radical duodenopancreatectomy on March 6, 1940, removing the distal third of the stomach, the entire duodenum and the head of the pancreas, with an antecolic gastro-

jejunostomy and implantation of the dilated common duct into the jejunum (Fig. 5). This was

or hypoglycemia nineteen months after operation. The second patient, on whom we performed a simi-

FIGURE 4. *Second Stage: Duodenectomy, with removal of part or all of the head of the pancreas. If a gastroenterostomy has not been done in the first stage, it must be done in the second stage.*

done for a carcinoma of the head of the pancreas that on section proved to be an islet-cell carcinoma without evidence of hypoglycemia. The patient, a

lar one-stage procedure in September, 1940, succumbed to a postoperative pneumonitis on the fourth day. The third operation with the one-

FIGURE 5. *One-Stage Radical Duodenopancreatectomy, with Antecolic Gastrojejunostomy and Implantation of the Common Duct into the Jejunum.*

forty-seven-year-old woman, had no postoperative complications, regained 20 pounds, and was free from any signs of recurrence, jaundice, cholangitis

stage procedure has been done too recently to be reported as a result.

Shortly after our first one-stage operation, Trim-

ble,<sup>41</sup> of Baltimore, independently performed a similar operation for a carcinoma of the ampulla. This patient was well and free from evidence of recurrence eighteen months after the radical operation.

But both the two-stage procedure and the one-stage procedure, as reported in the literature and in personal communications to me by surgeons who know of my interest in the subject, carry with them certain hazards and complications that must be eliminated and present problems that must be solved before these radical operations can be generally accepted. The two most serious complications are postoperative biliary and pancreatic fistulas (Table 3). In the 54 cases I have collected, the incidence of fistulas has been 10 biliary, 11 pancreatic and 2 duodenal. Duodenal and pancreatic fistulas usually close spontaneously, but biliary fistulas seldom do. The biliary fistula is due

very have been gathered from studies in dogs. It is generally agreed that in these experimental animals total pancreatectomy followed by survival with insulin therapy has resulted in fatty degeneration of the liver and alterations in blood-lipid level. Montgomery,<sup>43</sup> in his most recent work, corroborates previous studies showing that total ligation of the pancreatic ducts with complete isolation of the pancreas from any communication with the gastrointestinal tract results in the same alteration in the blood and liver lipid content and a fatty degeneration of the liver. He also corroborates the claim that administration of raw pancreas and inactivated pancreatic juice, in large amounts, will prevent these changes. Dragstedt<sup>44</sup> maintains that pancreatic juice will not prevent this disturbance in fat metabolism in pancreatectomized dogs but that raw pancreas will do so; he states that it i

to the cutting through of the silk or linen ligature used in tying off the common duct. It is undoubtedly a better procedure, when possible, to implant the severed end of the common duct into the loop of jejunum used in the gastrojejunostomy in the one-stage operation, or into the jejunal segment leading to the jejunojejunostomy in the two-stage procedure. Pancreatic fistula can be avoided if the open end of the dilated pancreatic duct is ligated carefully with silk and the V-shaped excision in the pancreas closed or the whole stump of the cut pancreas tied with a silk ligature, as advocated by Brunschwig and Clark.<sup>42</sup>

The question whether the maintenance of the flow of the external secretion of the pancreas into the gastrointestinal tract is essential to the welfare and life of the patient has been debated, especially in the last two years. Both experimental and clinical data, reported by various observers, are in disagreement on this important subject. Some investigators maintain that the external secretion of the pancreas contains the factor that is essential for the control of fat metabolism in the liver. Others do not agree with this statement. Almost all the experimental data in this contro-

not the choline or the lecithin in the raw pancreas that produces this effect, but that the active principle is a fat-free substance, obtained in an active, alcohol-soluble extract of the pancreas. He believes that this substance is a specific hormone and has named it "lipocaic." Very recently, in discussing this entire subject of lipocaic and exclusion of the external secretion of the pancreas from the gastrointestinal tract, Dragstedt<sup>45</sup> kindly gave me his most recent views on the subject:

You will be interested to know that all scientific workers are now willing to agree with us that the beneficial effect of lipocaic cannot be accounted for on the basis of its content of choline, lecithin or the generally nonspecific lipotropic action of proteins. Confirmation of our claims in this regard has come from a number of different laboratories, including the one at Toronto.

The claim of Montgomery and his associates that lipocaic is present in the external secretion of the pancreas cannot be considered as proved by the experiments that they present. In our first paper, we demonstrated conclusively on nine depancreatized animals that the administration of fresh, active pancreatic juice in amounts up to 1000 cc. per day not only did not prevent the onset of fatty livers in these animals but

actually accelerated it. Montgomery's claim that inactivated pancreatic juice, when given by mouth, exerts a protective action is not warranted by the data that he presents, in my judgment. I expect to refer to this in considerable detail in a forthcoming publication. The effect of complete occlusion of the pancreatic ducts on the incidence of fatty infiltration of the liver in experimental animals has yielded conflicting results in the hands of different workers. In our experience, the majority of such animals do not develop the extensive degree of fatty infiltration that is seen in the depancreatized dog in the same period. I believe that the discrepancy in the results of various investigators, as well as the variations in the appearance of fatty livers in individual duct-ligated dogs, depends very largely on the extent of degeneration in the pancreas that takes place, as well as on the diet that is given to these animals. Ligation of the pancreatic ducts results in extensive destruction of the pancreas, whereas diversion of the pancreatic juice to the exterior by means of an appropriate fistula may leave the pancreas quite intact. The fact that animals with pancreatic fistula do not develop fatty livers when the pancreas remains normal indicates that fatty infiltration of the liver is not due to the absence of pancreatic juice from the intestinal tract. The presence of a moderate degree of fatty infiltration of the liver in a minority of the animals following ligation of the pancreatic ducts seems, therefore, to be due to the atrophy of the pancreas that takes place in these animals. There is evidence that this atrophy affects the islets as well as the parenchyma in some cases.

Furthermore, our<sup>46</sup> studies of the fat digestion in patients with complete duodenectomy and total exclusion of pancreatic juice from the gastrointestinal tract have shown fat digestion of 80 to 85 per cent of a carefully measured fat intake, and in a patient who came to autopsy nine months after the radical operation, fatty degeneration of the liver was not found. Schnedorf and Orr,<sup>47</sup> in a recent study of 35 cases of carcinoma of the pancreas and 17 cases of ampullary carcinoma, found only 10 cases that showed fatty degeneration at autopsy. In only 1 of our 5 patients surviving for periods of five to twenty-eight months after the radical operation have we found a disturbed fat metabolism. This patient loses 40 to 50 per cent of her measured fat intake, but is able to digest her fat by the taking of a preparation called Holadin, a pancreatic substance particularly rich in lipase.

Thus, it is evident that the question of disturbed fat metabolism in a patient whose pancreas is completely isolated from the gastrointestinal tract is not as yet completely answered, and only a large number of patients surviving the operation from three to five years will provide the necessary data for an accurate statement in this regard. It may be necessary to renew the efforts to re-establish the communication between the pancreas and the gas-

trointestinal tract in the radical removal of these ampullary and pancreatic cancers. The proposal of Kauer and Glenn<sup>48</sup> to implant the stump of the pancreas into the posterior wall of the stomach may be the answer to this problem. In the meantime, the feeding of lecithin, pancreatic extract and lipocain to patients that show abnormal blood lipid levels and deficient fat digestion before and after the radical operation is clearly indicated to maintain fat metabolism and to prevent fatty changes in the liver.

The radical operation for these tumors of the ampullary region and pancreas, based on the principle of wide, en bloc removal of the tumors, as required in modern cancer surgery, is evidently in an evolutionary stage. Many more cases, with five-year survivals, will be required before valid claims can be made for the operations as done at present. But it must be remembered that these patients untreated have an average of six months' survival from onset of symptoms until death. Many of them are tortured with the uncontrollable itching of obstructive jaundice. The considerable risk of 30 to 35 per cent is justified if they can be made comfortable even for a year or two. If only these patients could and would be referred to the surgeon before they are studied to death, while the cancer is small and localized and before the patients are seriously ill with weeks of obstructive jaundice, a far lower operative mortality and a much longer survival would result.

## FRACTURES OF THE FEMUR\*

GEORGE W. VAN GORDER, M.D.†

BOSTON

THE treatment of fractures of the femur has undergone marked evolutionary changes in this generation. The advent of the Thomas splint, the introduction of skeletal traction, the ability to treat these fractures without immobilizing joints, the employment of the Smith-Petersen nail and the use of Russell traction are but a few of the milestones that have been passed in the improved care of these fractures. And in the presence of another war, with new instruments and technics of destruction, the treatment of fractures has again changed—this time of necessity, since patients in hospitals are no longer immune from attack and frequently must be hurriedly evacuated. The most practical form of treatment of femur fractures under war conditions seems to be the insertion of fixation pins above and below the site of fracture, reduction of the fragments and incorporation of the pins in a plaster cast or Roger-Anderson steel side bar.

In civilian practice, this method has not been used routinely for two main reasons: the frequency

of infection about the pinholes, and the danger of obtaining nonunion. In war, however, conditions are so different that the advantages of a method of treatment that allows almost immediate evacuation of the wounded soldier offset many disadvantages, even serious ones.

### TREATMENT IN CHILDREN

In children under six years of age, the popularly accepted form of treatment for fractures of the femur is overhead adhesive skin traction,<sup>1</sup> followed by a plaster cast. Whether both legs or only the injured one is suspended is optional. Those advocating suspension of both legs believe that there is less likelihood of torsion of the bone fragments, whereas those who suspend only the injured leg believe that the unsuspended one can be used to better advantage as an additional counterweight.

In children over six years of age, several methods of treatment can be used effectively.<sup>1</sup> The most popular appears to be skin traction with adhesive plaster in a Thomas splint, followed by a plaster cast. Another popular method is Russell's, which

\*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 13, 1941.

†Instructor in orthopedic surgery, Harvard Medical School; visiting orthopedic surgeon, Massachusetts General Hospital.

is described below as the procedure of choice in *intertrochanteric fractures*.

Some surgeons like Campbell<sup>2</sup> prefer to treat fractures of the femur in children by manipulation under anesthesia and application of a plaster cast. In all fairness to Campbell, it should be recorded that his results are exceptionally good, but it must also be stated that his same method in other hands has not yielded the same excellent results.

Most surgeons agree that open reduction is rarely indicated in children, since the broken femur of a child has a remarkable tendency to resume its normal shape and length if given the least opportunity. For this reason, the end results of femoral fractures in children are universally good.

#### TREATMENT IN ADULTS

##### *Fractures of Femoral Neck*

Fractures of the neck of the femur are considered emergency operative fractures at the Massachusetts General Hospital, and are treated as such. The same opinion holds true in some other well-known fracture clinics. The sooner a femoral-neck fracture is nailed, the better. This refers not only to the chances of securing bony union of the fracture but also to the patient's general welfare. In other words, if the patient's physical condition will permit, and it usually does, the operation of hip nailing is carried out at once, or as soon after the accident as possible—a matter of hours, not days.

Increasing experience with internal fixation of these fractures by means of the Smith-Petersen nail is yielding steadily improved results, so that this treatment is now universally accepted as the method of choice.

Experience has also shown that the Smith-Petersen nail is better and more efficient than Moore pins, wires or other kinds of nails in maintaining reduction, in decreasing the incidence of breaking, in migration and in the percentage of bony union obtained.<sup>1</sup>

The technic of inserting the Smith-Petersen nail, as well as the postoperative care, varies with the individual operator, and these subjects cannot be discussed in detail at the moment. Suffice it to say that the operative approach used at the Massachusetts General Hospital is through the lateral thigh muscles. A Kirschner guide wire is inserted into the femoral neck under x-ray control, and when the correct position of the wire has been obtained, a cannulated Smith-Petersen nail is threaded over it and driven home. Impaction of the fragments is the next procedure, followed by closure of the wound.

The postoperative care usually consists of one month in bed in Russell traction (for comfort),

followed by two weeks of lying free in bed, and then crutches, but no weight-bearing and no walking caliper splint. Of course, there are exceptions to this general rule.

##### *Intertrochanteric Fractures*

The ideal method of closed treatment for intertrochanteric fractures, in the opinion of many authorities, is Russell traction. Certainly, it is the most comfortable form of traction for the patient, and the most satisfactory from a nursing point of view. Its greatest disadvantage is that, to be effective, it must be carefully watched and adjusted, which means that nurses as well as doctors must understand its principles and must be able to correct any faulty mechanics that may appear.<sup>3</sup>

Russell traction accomplishes the two things desired in intertrochanteric fractures: it supplies traction in a comfortable manner with a minimum amount of weight, and it prevents external rotation of the femoral shaft by pulling through a flexed knee.

A word of warning should be sounded here: care must be taken to continue traction for ten weeks or longer, as a rule, to avoid a recurring coxa vara. Many intertrochanteric fractures buckle or sag after removal of traction. Thus, it is safer to maintain traction for a longer time and secure firm union, than to get the patient up earlier and trust in a walking caliper splint, which is nondependable.

However, a number of observers have recently noted that the mortality in cases of intertrochanteric fracture is rather high, higher certainly than that in cases of femoral-neck fracture, and this fact has led them to consider treating intertrochanteric fractures like neck fractures. These surgeons believe that the long confinement in bed with Russell traction is detrimental to health and favors pneumonia. Thus, Thornton, of Atlanta, Georgia, has devised a combination Smith-Petersen nail and plate that secures the intertrochanteric fragments in an admirable way and allows early convalescence, as in femoral-neck fractures.<sup>1</sup> The Thornton apparatus has proved its value, and can certainly be recommended in selected cases of intertrochanteric fractures. Whether it will prove suitable for all such fractures cannot yet be determined.

##### *Supracondylar Fractures*

Some clinics regard fractures of the femoral shaft as definite indications for open operation, and I think it fair to say that more and more surgeons are gradually adopting this point of view. However, the great majority of surgeons who treat fractures do not have the facilities or equipment to carry out major operative procedures on all their cases, and until they do it will be necessary

for most surgeons to continue to employ conservative measures. I believe that the operative treatment of fractures is the ideal for which one should strive, but at the present time only a handful of clinics in the United States are properly qualified to make operation the routine procedure on all fractures.

On the other hand, certain fractures should be considered definitely operative, such as those of the neck of the femur, the olecranon, the patella, extensive bumper fractures and so forth, and to these I add another—low supracondylar fractures of the femur, with marked displacement. The difficulties of controlling the bone fragments in this type of fracture by conservative or closed methods are so great as to be unjustified, and open reduction with internal fixation is the answer to the problem in my opinion.

When, however, low supracondylar fractures are badly comminuted and not suitable for bone plating or banding, nonoperative methods must be employed, and the best conservative method of treatment is the use of skeletal traction from the tibial tubercle through the knee joint, with the leg resting in a Thomas splint and Peirson attachment.<sup>1</sup>

In such cases, the Kirschner wire is made to pull through the slightly flexed knee joint in a line as nearly parallel to the plane of the tibia as possible. Thus, the traction force is transmitted through the joint with the least amount of strain on its ligaments. A common fault, and a serious one, is to flex the knee too much, which vitiates the pulling force if it is transmitted along the line of the tibia, or causes a dangerous shearing force on the joint if it is transmitted in the line of the femur.

### *Fractures of Shaft*

The most efficient closed method of treating fractures of the shaft of the femur is by means of Kirschner-wire traction in the femoral condyles, with the leg resting in a Thomas splint and Peirson attachment.<sup>1</sup>

The traction element is of the utmost importance and should be accomplished through skeletal rather than through dermal attachments. One of the lessons that long experience has taught is that traction by adhesive tape attached to the skin is neither reliable nor adequate for the treatment of fractures of the shaft of the femur, unless used in conjunction with Russell traction, when the amount of pull exerted by the adhesive tape is diminished by half because of the system of pulleys used.

Some surgeons<sup>3, 4</sup> consider Russell traction suitable and adequate for all fractures of the shaft of the femur and preferable to all other closed meth-

ods. Certainly, the method has been growing in popularity, but most surgeons of my acquaintance believe that it is suitable only for upper-third and intertrochanteric fractures—not for lower-third or supracondylar ones.

In a recent article, Lewis<sup>4</sup> states that Russell traction is the method of choice for all fractures involving the shaft of the femur and that skeletal traction should be discarded as a procedure in handling femur fractures. Such conclusions are not at all justified in my judgment, but they show that there is some difference of opinion among surgeons concerning the ideal treatment for fractures of the shaft of the femur and that Russell traction is contending for honors with skeletal traction as the method of choice.

In a recent study<sup>5</sup> of end results in the treatment of 58 fractures of the shaft of the femur by skeletal traction at the Massachusetts General Hospital, the following data were obtained: the average hospital stay of the patients was eleven and a half weeks; there were 3 cases of nonunion; shortening of the femur was present in 31 per cent, the average being 2.1 cm.; knee-joint motion was limited in 25 per cent, the average limitation being a total range of 76°; the average time that elapsed between the date of injury and the date when the patients returned to work was seven and a quarter months; and the end-result rating showed 87 per cent good, 5 per cent fair and 8 per cent poor.

### SUMMARY

Certain standardized forms of treatment for fractures of the femur are proposed, as follows: for fractures of the femoral neck, a Smith-Petersen nail; for intertrochanteric fractures, Russell traction; for low supracondylar fractures, open reduction or, if that is impossible, skeletal traction from the tibial tubercle through the knee joint in conjunction with a Thomas splint and Peirson attachment; and for fractures of the shaft of the femur, Russell traction for upper-third fractures, and skeletal traction with a Thomas splint and Peirson attachment for mid-third and lower-third fractures.

In hospitals fully equipped for operative procedures on all kinds of fractures, where fracture services are established and the treatment of fractures is considered a specialty, open reduction with internal fixation is the ideal form of treatment for all fractures of the femur in adults.

## DISCUSSION

A PHYSICIAN How much weight should be used in traction?

DR CHESTER L. SMART (Laconia) I should like to ask the status of the bone graft in intertrochanteric fractures. I have heard nothing about this lately, but the procedure was formerly quite popular.

DR JAMES B. WOODMAN (Franklin Falls) At our hospital we had some patients with intertrochanteric fractures to whom we applied traction by a plaster cast from the foot well up to the thigh, with the leg in full extension, plenty of padding, a little traction and a large amount of internal rotation. This position was maintained by the placing of a strip of wood on the bed at right angles to the leg under the angle, and the incorporation of the strip in the plaster cast, to maintain the internal rotation and slight traction.

It was a fairly comfortable apparatus and we succeeded in getting very good results in several cases. But I am not yet ready to report my series of half a dozen cases.

DR TIMOTHY F. ROCK (Nashua) I have seen a few cases of intertrochanteric fracture in which the Moore pin was used with good results. In 1 case, however, the pin slipped soon after operation. The other 2 patients did very well, without any additional apparatus.

DR EMERY M. FITCH (Claremont) Dr Van Gorder should be complimented on bringing to our attention the use of skeletal traction in contrast to skin traction with adhesive tape. If the former were used more, I think the results would be far better in the treatment of fractured shafts.

I should like to know a simple method of immediately reducing the fractures that slip by, I have trouble in getting them back.

DR EDGAR J. THIBODEAU (Berlin) I should like to know why patients are kept in bed for a month postoperatively. I thought the idea of the Smith Petersen nail was to get the patient up as soon as possible.

DR GEORGE W. VAN GORDER (closing) The first question concerned the amount of weight used in reducing fractures of the femur. That depends entirely on whether Russell traction or skeletal traction is used. The former procedure, as a rule, requires 10 to 15 pounds. This means, of course, that double that amount of weight is actually exerted on the femur, owing to the use of the Russell pulley system. Personally, I have never used more than 15 pounds with Russell traction, and have found this always to be adequate.

When it comes to the matter of skeletal traction in fresh fractures, one does not need to use more than 15 pounds of weight to start with, and it is customary to decrease this amount gradually. If the fracture is an old one, however, or if callus has already started to appear, the weight must be increased and can go up as far as 40 pounds.

The use of autogenous bone grafts in fractures of the neck of the femur is an important matter, but it concerns chiefly the fractures of long standing or with nonunion, rather than fresh fractures. For fresh femoral neck fractures, the percentage of excellent results following the use of the Smith Petersen nail alone is so high (80 to 85 per cent) that bone grafting as an initial procedure has not been considered necessary.

King, a well known surgeon in Australia, believes, however, that the percentage of unions in these fractures can be definitely increased by the use of a bone graft in addition to the Smith Petersen nail. Therefore, when he does his operation in a fresh case, he directs two Kirschner wires into the neck, one fairly high and the other fairly low, and over the high wire he threads a cannulated Smith Petersen nail which gives his fixation, over the lower wire he threads a  $\frac{1}{8}$  inch drill, which cuts out a smooth tunnel extending across the fracture line into the femoral head. Into this tunnel, he then inserts a well fitting graft from either the tibia or the fibula. This means that he not only has immobilized the fragments of the femur but has also bridged the fracture line with a bone graft. This operation has been done a number of times in our clinic with success, although we have employed it only in cases of nonunion.

Dr Woodman spoke of intertrochanteric fractures treated in plaster casts with a little pull. Certainly, that method seems to be a logical one if one decides to allow the patient to lie in bed for ten or twelve weeks. I have never employed traction on a leg plaster cast, because I have been afraid of exerting pressure on the dorsum of the foot where too much pressure causes pain and injury to the soft parts. The plaster cast, however, can easily control the desired positions of internal rotation and abduction. But why use any plaster at all in intertrochanteric fractures if one can use a simple method, like Russell traction that will keep the patient perfectly comfortable, allow a certain amount of moving about in bed and greatly facilitate nursing care? Russell traction prevents external rotation because it pulls through a flexed knee that is held by a hammock in the vertical plane. With the patella pointing directly upward and with the knee flexed the patient's leg is prevented from externally rotating and only half the weight that is necessary in other traction methods need be used.

Dr Rock spoke of Moore pins which might be used in intertrochanteric fractures instead of the Smith Petersen nail. That is a very practical point, and one that should be considered when open reduction of the fracture is believed to be indicated. We all know that intertrochanteric fractures are often comminuted and we also know that the cortex of the femur is not always very strong, especially near the line of fracture. Therefore, when one attempts to insert a Smith Petersen nail through the lower femoral shaft fragment close to the line of fracture, the shaft is very likely to split. To avoid this we are in the habit of cutting three small grooves in the bone with small sharp osteotomes, these correspond with the flanges of the Smith Petersen nail and, in this way, safeguard the cortex from splitting. This is also a routine procedure in the nailing of femoral neck fractures. I have never used pins in intertrochanteric fractures, and, although I can appreciate the fact that they would not have the same tendency to split the femoral shaft, I wonder if they would provide sufficient fixation of all the fractured elements. As an answer to the problem of internal fixation of intertrochanteric fractures, Thornton, of Atlanta,

devised the method that I described in my paper. This method has been successful in our hands as well as his, and the method is certainly indicated in selected cases.

Dr. Fitch asked how immediate reduction of fractures of the shaft of the femur could be accomplished. I have not been in the habit of using immediate reduction of fractures of the femur but have counted on traction, for the most part, to reduce the fragments. Sometimes, an attempt to manipulate the fragments in bed under anesthesia is successful when rather marked displacement is present. For the most part, however, the results in our clinic have been due to traction alone.

Dr. Thibodeau asked why patients with fractures of the femoral neck are kept in bed so long. The postoperative

care of these patients varies with the individual surgeon. In the Orthopedic Clinic of the Massachusetts General Hospital, we believe that a month's rest in bed is not a handicap for such a patient, because during that time, he is allowed to sit up in bed or roll over on his side and thus to move about to a certain extent. It should be noted that, with this regime, pneumonia is a very unusual complication. On the other hand, we have seen tragedies result from getting patients up too early, and there seems to be no point in forcing them out of bed on the second or third day. The idea of the Smith-Petersen nail is not so much to get the patient up as soon as possible but to render him comfortable and ensure eventual bony union of his fracture.

## MEDICAL PROGRESS

### MUMPS

CONRAD WESSELHOEFT, M.D.\*

BOSTON

MUMPS is essentially a disease of childhood. In Massachusetts, 88.6 per cent of the cases reported from 1933 to 1937 involved children less than fifteen years of age.<sup>1</sup> One attack usually affords a permanent immunity, but almost every general practitioner can cite cases of second attacks. It can occur at all ages, and it occurs throughout the year both in endemic and epidemic form. There is a tendency for the cases to increase in the cooler months, epidemics being particularly apt to take place toward the end of winter and in early spring. Actually, there is no adequate explanation of how the disease keeps going year after year. However, it is a fact that approximately nine tenths of city inhabitants above the age of sixteen have had mumps, whereas in widely scattered farming communities remote from cities a much smaller percentage of the community has had the disease at this age. In some regions, only one young adult out of ten has had mumps. This explains why pupil nurses and military recruits from the country are apt to come down with the disease within the first three months of their training.<sup>2</sup> Thus it is that a childhood disease may become a military problem of more serious import to a rapidly recruited army than to a standing army of seasoned troops.<sup>3</sup> Cities appear to be the main reservoirs of this infection. Here the virus is kept alive by active clinical cases, by subclinical cases or by actual carriers—whose existence has never been proved. So far as is known, the disease is confined to man.

The knowledge of virus diseases is still rudimentary, and it was only in 1934 that Johnson and Goodpasture<sup>4</sup> proved the existence of the virus of mumps. So far, they have shown that this filterable virus exists in the saliva during the first forty-eight hours of the disease, that it is resistant to neutral glycerin, freezing and drying, and that it can be transferred to *Macacus monkeys* through numerous generations and back again to man. The transfer to the monkey was effected by direct injection into the parotid duct. The transfer to man was accomplished by spraying into the mouths of healthy nonimmune volunteers. It is of interest that transfers were unsuccessful in summer. These experiments have been confirmed by Findlay and Clarke,<sup>5</sup> but no further progress has been made. Attempts to grow the virus on the chick embryo or by other means have so far been unsuccessful. Thus it is that, in spite of the auspicious start in the demonstration of the etiologic agent, the threads of progress must be picked up through the epidemiologic and clinical studies that have made possible a better understanding of this disease.

In spite of the establishment of the virus nature of this malady, there is still no practical diagnostic laboratory test that can stand alone, such as a positive diphtheria culture, and there is no means of bringing about an active immunity other than by acquiring the disease in its natural form. Nevertheless, progress achieved by the investigators at Vanderbilt University gives promise of advancement in both these directions. When it is realized that, in World War I, mumps stood third among the diseases causing time lost in hospital,<sup>6</sup> ranking next to venereal disease and influenza,<sup>7</sup> the

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

\*Clinical professor of communicable diseases, Harvard Medical School; physician-in-chief, Haynes Memorial, Massachusetts Memorial Hospitals.

incentive for further research should be forthcoming.

Mumps is looked on by some today as a systemic disease, whereas it has usually been considered a local disease of the salivary glands with occasional "metastases to other organs." There is reason to believe that the portal of entry of the virus is by the mouth, but the channel by which it finds its way to the salivary glands is not known. Presumably, it is a roundabout course involving the blood stream rather than a direct one by way of the duct orifices. This newer conception is based on the long incubation period of eighteen days,<sup>8</sup> the findings in pathologic specimens,<sup>9</sup> and recent advances in other virus diseases with neurotropic properties.

Philibert<sup>10</sup> has gone so far as to propound the idea that the virus of mumps may find its way first to the central nervous system, where, being of a low neurotropic order, it tends to create little disturbance, but after an incubation period in the central nervous system finds its way through the blood stream to the salivary glands. Here, the cytotropic properties of the virus are exerted, and here it is excreted in the saliva. Although this extremely speculative hypothesis presents many flaws, one must give credit to this French author for the first serious explanation of the various sequences of events that may take place in this disease. In this way, he accounts for the facts that orchitis, ovaritis, encephalitis and pancreatitis can precede, accompany or follow the involvement of the salivary glands and that mumps can occur in these remote organs without any appreciable involvement of the salivary glands. The diagnosis in these cases is established by the purely circumstantial evidence of an exposure, the proper incubation period and the course pursued.<sup>11</sup> Philibert brings to his support the frequent finding of a pleocytosis in the spinal fluid in cases of mumps that show no clinical symptoms of meningeal irritation. There is, of course, no proof that such pleocytosis represents actual virus invasion of the central nervous system in these cases. Indeed, the virus could just as well undergo its incubation period somewhere in the lymphatic system or else, where, as seems to be a possibility in poliomyelitis, gaining access to the central nervous system in only a certain proportion of cases. Regardless of the questionable premises on which Philibert's thesis is based, it has stimulated the idea that mumps is to be looked on as a systemic disease with a variety of manifestations rather than a local disease with "complications." It is of interest to note that in a careful study of 100 cases by Greene and Heeren<sup>12</sup> nonsalivary manifestations were found in 43.

The parotid glands are involved in the vast majority of cases, and bilaterally in about 70 per cent. The submaxillary glands are frequently involved, and sometimes the sublinguals. There is clinical evidence to support the idea that infectiousness may precede the glandular swelling by at least twenty-four hours. How long this infectiousness lasts is unknown. The results of the experiments by Johnson and Goodpasture<sup>1</sup> indicate that it is of only a few days' duration, but for practical purposes a week from the onset, or for the duration of the swelling, is the usual rule for isolation.

Other glands in the body may become invaded—first of all, the gonads, especially in the male. Next in order of frequency come the pancreas, the breasts both in males and females, and the thyroid, thymus, lachrymal and Bartholin's glands.

Blood studies indicate that a normal blood picture is often present, but that a lymphocytosis is the rule. However, when glandular inflammation becomes very acute the polymorphonuclear cells tend to increase. This is especially true in severe orchitis.

The lesions within the parotid gland of experimental mumps in monkeys have been described by Johnson and Goodpasture.<sup>4</sup> There are edematous swelling of the gland and its surrounding tissue, owing to vascular injury, and parenchymal lesions, with disintegration of the acinar cells and infiltration of mononuclear cells and lymphocytes. Healing takes place by removal of the debris and regeneration of the acinar epithelium, which restores the gland without scarring. Reports on the pathologic specimens obtained from human mumps are recorded by Delater<sup>13</sup> and deLavergne and his associates.<sup>6</sup> These findings coincide with those found in the monkey. The pathology of orchitis was described by Wolbach in an article by Smith.<sup>14</sup> Manca<sup>15</sup> also gives his findings and compares the pathology with that found in orchitis from other causes.

Orchitis rarely occurs before puberty. At and above the age of puberty, the incidence is 18 per cent, but with epidemic strains there is a wide variation, which makes it very difficult to evaluate preventive measures. It was thought at one time that the virus was carried by the hand from the mouth to the penis, and that it traveled up the urethra to the testicle. This theory was disproved by the careful experiments of Radin<sup>16</sup> at Camp Wheeler. Both Dukes<sup>17</sup> and Radin have shown that strict bed rest did not reduce the incidence of orchitis. Trauma to the testicle during the incubation period and during the priortitis has been thought to precipitate testicular involvement. Dismounted drill has been recommended for the cavalry when mumps is epidemic, but the figures

given in Table 1 fail to substantiate this.<sup>18</sup> Adhering to the trauma theory, Place<sup>19</sup> advocates thigh bridges with cotton nests and suspensories; he reports a 5 per cent incidence of orchitis with such treatment, but fails to give the number of cases so treated. Equally good results have been reported without such protection with measures since proved to be ineffective.<sup>20</sup>

The administration of convalescent serum at the onset of mumps is claimed to be effective in

TABLE 1. *Incidence of Orchitis.*

PERSONNEL	CASES OF MUMPS	CASES OF ORCHITIS	PERCENTAGE OF ORCHITIS
Infantry . . . . .	1106	249	21.6
Cavalry . . . . .	162	36	22.2
Miscellaneous Army and Navy . . . . .	6576	1119	17.1
Civilian . . . . .	309	64	20.7

Percentage . . . . .			18.0

reducing the incidence of orchitis. DeLavergne and Florentin,<sup>21</sup> Cambessédès,<sup>22</sup> Odenius<sup>23</sup> and Iversen<sup>24</sup> have reported excellent results from this method, but the equally good results reported at one time from the routine use of diphtheria anti-toxin in mumps<sup>3</sup> make one hesitate to accept this treatment as one of undoubted efficacy. Convalescent serum has certainly not proved efficacious in other virus diseases when administered after the period of incubation — except in huge doses, which are entirely impractical. Thalhimer<sup>25</sup> asserts that doses of 40 to 60 cc. "will alleviate complications such as orchitis and oöphoritis," but he supplies no figures to substantiate this claim.

The treatment of orchitis consists in affording as much relief as possible by the local application of heat or cold. Some patients much prefer heat, and it has never been established that either cold or heat prevents the process from getting worse. Support to the testicles is comforting. If the condition becomes severe, all local applications are futile. Indeed, a ½ gr. of morphine may not control the pain. If allowed to go on, the pressure within the tunica albuginea becomes so great that pressure necrosis takes place and atrophy follows. One can avoid this by making an incision through the scrotum under a general anesthetic, exposing the testicle and making one or more small incisions of the tunica albuginea. Wesselhoeft and Vose<sup>26</sup> are about to report on 27 patients with mumps orchitis, 20 of whom have been followed up. In 10 severe cases operated on, only 1 patient developed atrophy; in this case, operation was performed too late to be effective. In 10 mild cases in which the patients were not operated on, no atrophy developed. Without surgical interference, the incidence of atrophy in all cases

was 54 per cent.<sup>18</sup> Consequently, the authors conclude that atrophy occurs only after severe cases, and that by early operation in such cases atrophy can be avoided.

The diagnosis of ovaritis is much more difficult than that of orchitis. Especially is this so in mild cases. Consequently, the incidence is much lower than that in orchitis. Repeated chills and marked fluctuations of pyrexia are common to both conditions. There is no limiting layer in the ovary comparable to the tunica albuginea. Therefore, any permanent damage is unlikely to occur. Daléas<sup>27</sup> and Béclere and Demange<sup>28</sup> have described the menstrual irregularities that follow mumps and ovaritis.

Prostatitis has been reported by Greene and Heeren<sup>12</sup> and also by Robinson.<sup>29</sup> Epididymitis frequently occurs with orchitis, but it may occur alone. It is less painful than the gonorrheal form and subsides spontaneously. Mastitis can occur in both the male and female, and is usually mild.

Pancreatitis is not uncommon. Farnam<sup>30</sup> and Sylvest<sup>31</sup> have reviewed the subject. Sailer<sup>32</sup> found jaundice in 4 out of 14 cases. In severe cases, the gland can be palpated through the abdominal wall. Mommsen and Mayer<sup>33</sup> and Gundersen<sup>34</sup> have discussed the possibility of mumps as a cause of diabetes. The subject offers much of interest, but the available evidence is not convincing.<sup>20</sup>

The influence of mumps on the nervous system is a subject that has come into recent prominence as a result of Philibert's<sup>10</sup> thesis. Clinical evidence of meningeal irritation occurs in 10 per cent of the cases,<sup>12, 35-38</sup> usually to only a mild degree. The findings in the spinal fluid are the same as those in preparalytic poliomyelitis. Indeed, the circumstantial evidence of mumps is the only means of differentiating the two conditions. During epidemics of mumps in the summer and fall, meningeal irritation is frequently mistaken for poliomyelitis because of the headache associated with rigidity of the neck and spine. When the encephalitis precedes the parotitis or is the only manifestation of the disease, the diagnosis hinges entirely on the circumstantial evidence of exposure.

"Latent encephalitis" is a term used to designate an increase in the cells of the spinal fluid, chiefly lymphocytes, without any clinical signs or symptoms of meningeal irritation. Silber<sup>38</sup> found a pleocytosis in 30 such cases. Finkelstein<sup>39</sup> found 6 at the Willard Parker Hospital, and in these the cell count ranged from 15 to 880. I<sup>11</sup> have reported one such case, with 400 cells per cubic millimeter. Herrick and Dannenberg<sup>40</sup> have shown that a pleocytosis may occur without signs of meningeal irritation in other infectious diseases, but the cell counts reported in these other infec-

tions never reached the numbers found in mumps. Whether this pleocytosis is really a manifestation of an encephalitis or another form of lymphocytic choromeningitis is unknown. Certainly, in poliomyelitis and in mumps, a true encephalitis may take place as determined by the pathological findings. Myelin degeneration has been found in some cases of mumps, and in others it is not in evidence.<sup>41</sup> There is a confusing note in the pathological and clinical reports on mumps encephalitis because the records frequently suggest that the attack activated an encephalitis of the lethargic or other type.<sup>42-44</sup> Especially is this so in those rare cases exhibiting spinal nerve paralyses, and when the onset follows many days after the mumps.<sup>41</sup> Donohue<sup>44</sup> in an excellent review of the subject maintains that although those cases exhibiting protracted encephalomyelitis are probably not due to the mumps virus, it is unnecessary to postulate an additional factor in all fatal cases. He reports an encephalitis that appeared eight days after a mumps proctitis. The characteristic perivascular demyelination of postinfectious encephalitis was found, but this fatal case was complicated with a confluent bronchopneumonia, and therefore can not be considered as pure mumps. Until an accurate laboratory diagnostic test for mumps is forthcoming, this question can never be settled.

Mumps encephalitis is frequently only a mild affair of a few days' duration. When there is only slight evidence of meningeal irritation, there is no necessity of doing a lumbar puncture. On the other hand, when the condition is severe, not only is a lumbar puncture indicated but spinal drainage as well, and this may have to be repeated.

Facial nerve paralyses of a temporary character have been reported.<sup>45</sup> Young<sup>46</sup> reports a unique case of bilateral optic neuritis, with complete blindness coming on thirteen days after mumps, in a ten-year-old boy who recovered completely. This temporary character of mumps neuritis is of significance in relation to mumps deafness, which is permanent. Therefore, the question arises whether the deafness of mumps should be ascribed to a neuritis of the auditory nerve. The rarity of this condition necessitates much speculation from meager facts. It is not dependent on the presence of an encephalitis. Consequently, it cannot be ascribed to a radiculitis. It may be unilateral, occurring on the opposite side from a unilateral parotitis. It may be ushered in with the acute symptoms of Ménière's disease. Mauthner<sup>47</sup> found islands of deafness in the milder cases. All this suggests that the deafness of mumps might well be attributable to damage within the cochlear, a true labyrinthitis, rather than to a primary in-

jury of the cochlear branch of the auditory nerve. The static labyrinth and the cochlear can be involved simultaneously or independently, as in the epididymis and testicle. This subject has recently been reviewed.<sup>20</sup>

There has been much discussion regarding the value of convalescent mumps serum during the acute stage of mumps. With the onset of the symptoms, the virus has already become attached to the cells of the involved organ and is well out of reach of antibodies supplied in the form of therapeutic serum. One has but to recall the enthusiasm once entertained for convalescent serum in poliomyelitis and the present lack of evidence of its value. In very large doses, convalescent serum is effective in the acute stage of measles, but only in such enormous doses as to be impractical. Since the parotitis itself rarely produces enough discomfort to warrant any such drastic measure, the question arises whether it would be helpful in combating such a condition as orchitis or encephalitis. Whether the administration of serum could prevent a mild case from developing into a severe case has not been established. Theoretically, it is unlikely that it would be of benefit, since the virus is already attached to the cells. Certainly, in severe cases, incision of the tunica and lumbar drainage are of infinitely more value as protective measures and afford prompt and genuine relief. The question whether serum administered at the onset of the proctitis prevents the involvement of other organs has been discussed above.

The prevention of mumps by the injection of convalescent mumps serum soon after exposure is an entirely different matter and is of established value. The long incubation period is of distinct advantage. Zelig,<sup>48</sup> Cambessédès,<sup>22</sup> Thalheimer,<sup>25</sup> Kutscher,<sup>49</sup> Dwyer<sup>50</sup> and Regan<sup>51</sup> have all reported protection of 100 per cent or nearly so. Brenberg and Ostroff<sup>52</sup> obtained a morbidity of 15 per cent in those given serum as against a morbidity of 39 per cent in the controls. Lyday<sup>53</sup> lost his enthusiasm for serum after injecting 86 persons in a prolonged epidemic at a children's hospital, where he obtained 11 failures, 6 of whom had re-exposures to the disease and received more than one injection of serum. Most authorities prefer serum obtained by bleeding two weeks after the disease has subsided. Persons exposed should receive the serum within a week after exposure. It is of the utmost importance to emphasize the fact that the protection afforded by the serum cannot be expected to last for more than fourteen days, and its use should be governed accordingly. It is therefore valuable as a means of preventing an epidemic but of very little value once an epidemic

is under way. This is of particular significance from a military point of view. Protective measures undertaken in schools either are entirely ineffective or, if effective, merely postpone the disease to a more disadvantageous period in life. From the standpoint of the individual and from the standpoint of national defense, there is a distinct advantage in having mumps between the ages of five and ten.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28131

#### PRESENTATION OF CASE

A nineteen year-old garage mechanic was admitted to the hospital because of a bad taste in his mouth, nausea, vomiting and abdominal pain.

The patient was quite well until about sixteen days before entry, when he returned home from skating feeling chilly and unwell. He had a slight cough, for which he took some aspirin and went to bed. The next day, he raised mucoid sputum and developed anorexia, with slight nausea. He stayed away from work, and in the next week became aware of a persistent 'bad taste' in his mouth, which he could not further describe. Thin, mucoid saliva seemed to collect in his mouth, and when he swallowed this, he became nauseated and vomited. In the week preceding entry, he continued to vomit frequently. Transient episodes of periumbilical pain appeared, coming on irregularly at any time, each lasting for only a few minutes. The pain and the vomiting were not relieved by the milk diet and bed rest prescribed by one physician, or by the "chalky" and liquid medicines prescribed by another, who diagnosed "peptic ulcer." At no time in the illness was blood coughed up or vomited, or were there any urinary symptoms, headaches or edema.

The family history was irrelevant. The patient had had nocturia (three or four times each night) all his life," always keeping a bedpan by his bed. In the nine months preceding his illness, he worked in garages, cleaning car upholstery with carbon tetrachloride. The fumes of this chemical seemed to nauseate him, making him feel faint. A week before the onset of his illness he changed jobs, to wash automobiles in a room where a spray gun using amyl acetate solvent paints was employed. He wore no mask, and complained that he often felt like vomiting.

On admission, the patient appeared well nourished but pale, weak and somewhat dehydrated. His breath was urinous. There was slight bleeding from the lower gums about the incisors. The buccal mucous membranes were pale, and the tongue was covered by a thick, dirty yellow white coat. The submental lymph nodes were enlarged, but not tender. The heart was of normal size, with a blowing systolic murmur audible all over

the precordium, loudest at the apex and over the pulmonic area. The lungs were normal. Tenderness was present in both flanks and costovertebral angles, and in the right upper quadrant of the abdomen. The extremities seemed quite weak.

The temperature was 98.6°F, the pulse 70, and the respirations 20. The blood pressure was 135 systolic, 70 diastolic.

Examination of the blood showed a red cell count of 1,900,000 with 50 gm hemoglobin, and a white-cell count of 13,800 with 89 per cent polymorphonuclears, 6 per cent lymphocytes and 5 per cent monocytes. The blood chlorides were 925 milliequiv, and the carbon dioxide combining power was 18.7 milliequiv per liter; the nonprotein nitrogen was 290 mg, the blood urea nitrogen 225 mg and the phosphorus 145 mg per 100 cc. The van den Bergh reaction was normal.

Examination of the urine showed a specific gravity of 1.015, a +++ test for albumin and a sediment with 2 or 3 white blood cells, 80 to 100 red blood cells and occasional granular casts per high-power field.

A roentgenogram of the abdomen showed one air-filled loop of intestine in the left lower quadrant, suggesting sigmoid, although a dilated loop of the small intestine could not be ruled out. Intravenous pyelograms showed kidneys of normal size and shape, with no excretion of dye over a period of forty-five minutes.

The patient was given 1500 cc of fluid intravenously. The next morning, he showed signs of periorbital edema, without swelling of the ankles. Extreme weakness and exhaustion became progressively worse during the day. Because the patient developed a Chvostek sign, he was given intravenous calcium gluconate. Following a second venoclysis, he developed signs of pulmonary edema. At this time, a roentgenogram of the chest showed fine mottling of the middle two thirds of the lower half of the lung fields, with a ground glass appearance. The heart appeared only very slightly enlarged, and the hilar vessels were of normal size. Toward evening of the second day, the pulse rose to 80, and became weaker, gradually failing. Caffeine sodium benzoate was used without avail. Death occurred at the end of the second hospital day.

#### DIFFERENTIAL DIAGNOSIS

DR ALFRED KRINES. In this patient, who had previously been in good health and who developed an illness from which he died in uremia within eighteen days, the first question one has to decide is whether this rapidly developing uremic state was due to intrinsic disease of the kidney or to some extrarenal lesion such as high intestinal

obstruction, which may simulate the uremic syndrome. This condition is occasionally called "achloremic uremia" because of the extensive loss of chlorides through persistent vomiting. Certainly, the facts as presented are consistent with such a diagnosis. In favor of it are the persistent nausea, the vomiting, the abdominal pain, the nitrogen retention and the low blood chlorides. Furthermore, there is a statement about a dilated loop of bowel. May I see the films?

There seems to be a dilated loop of bowel, but whether large or small bowel I do not know. However, it seems to me that there are more facts against the diagnosis of high intestinal obstruction than there are in favor of it. In the first place, the pain as described seems rather mild. Moreover, during the first week of the illness, there was no mention of pain at all. It appeared during the second week, seemed to be transient, lasting only a few minutes, and was not very severe. In addition, the degree of nitrogen retention seems unusually high for intestinal obstruction. Finally, the degree of anemia seems to exclude that diagnosis quite well. The patient was ill for only sixteen to eighteen days. This degree of anemia, if associated with an intestinal lesion, must have been due to rather severe hemorrhage, and there is absolutely nothing in the record to bear that out. So that I shall have to discard the diagnosis of intestinal obstruction as a cause of this uremia and assume that this was some form of intrinsic kidney disease.

The picture is entirely consistent with such a diagnosis. Many uremic patients may simulate cases of intestinal obstruction and, as a matter of fact, are not infrequently admitted from the Emergency Ward to the Surgical Service. I, myself, have seen a number of patients in uremia admitted to the Surgical Service because of abdominal pain and vomiting. Drs. Failla and Chapman<sup>1</sup> collected a group of such patients and called attention to this clinical syndrome. The clinical picture, therefore, is entirely consistent with primary renal disease. Other symptoms attracting our attention to the urinary tract are the long history of nocturia and the hematuria found on one urinalysis. The degree of nitrogen retention and anemia seems in favor of a renal lesion. I think that this patient died of nephritis. I should like to be able to stop here because that is as far as one can safely go with the information that has been given. It is always a guess to try to predict the histology of a renal lesion when one is presented with a patient dying in uremia. Uremia, regardless of the type of renal disease, is always the same, and without more in the way of clues than we have here, one must proceed on pure specu-

lation. However, I have to make some sort of histologic diagnosis.

In the first place, I cannot be sure whether renal disease was acute or chronic, since one can argue for either. In favor of a chronic lesion there are a number of factors, the first of which is the long history of nocturia, which was said to have been present during most of the patient's life. That may have been due to renal disease, but it may have been a habit that the patient developed. Many patients have nocturia of this kind without renal disease. It would have been extremely helpful to have had a urinalysis before this last illness. Also in favor of a chronic lesion is the very short duration of the final illness. It is unusual, although not impossible, for a patient to die of acute renal disease in so short a time. Most nephritic patients live a good deal longer than this. Another factor is the slight degree of anemia. Most patients with acute nephritis do not develop severe anemia in so short a period.

What are the factors in favor of an acute lesion? In the first place, the patient had always been well and had had no previous disability. The degree of hematuria recorded is more in keeping with an acute or subacute lesion than with a chronic one. Somewhat more in favor of an acute lesion is the absence of hypertension, although it is the rule to have hypertension with both acute and chronic renal disease. Acute pulmonary edema, which this patient developed, occurs commonly during the course of acute nephritis; if it occurs in chronic nephritis, it is much more likely to be associated with a fair degree of hypertension, which this patient did not have. Finally, it seems to me that the most important factor in favor of acute nephritis is the fact that the patient is stated to have had a normal-sized pair of kidneys by pyelogram. I do not know how accurate this observation is, but from what I can see in the film they look quite normal. I wish some one from the X-ray Department were here to assure me that that is an accurate observation because I am laying great stress on the fact that the kidneys were of normal size.

It would be helpful to know whether the urinary output was diminished or normal. In chronic renal disease, the nonprotein nitrogen is very much elevated with a normal urinary output, and in acute disease there is often oliguria or anuria.

DR. J. H. MEANS: The urinary output was 500 cc. on the only day it was possible to measure it.

DR. KRANES: That is not a great deal. If it was difficult to decide between acute and chronic nephritis, it seems even harder to determine the nature of the lesion. Statistically, the most likely diagnosis at this age is glomerulonephritis and

on the whole I think that the history is more consistent with an acute glomerulonephritis than with any other type of lesion. It seems to have been preceded by an upper respiratory infection, following which signs of uremia developed very rapidly. The hematuria is more in keeping with that, and as I say, glomerulonephritis is statistically the most probable diagnosis.

Another type of renal disease to be considered, and one for which there is no evidence, is acute pyelonephritis. One would not expect that to produce death in so short a time, and so far as chronic pyelonephritis goes, there is absolutely no history on which we can base that diagnosis—no chills, fever or pyuria, and a normal-sized pair of kidneys by x-ray study.

Could this have been a congenital malformation, such as bilateral megaloureters? If the patient had such an abnormality, I do not know how to do any more than guess it. There is no evidence.

Still another possibility is congenital cystic disease. No tumor masses were felt abdominally, and by x-ray examination the outline of these kidneys appeared smooth and not lobular; consequently, I must discard this diagnosis.

One other type of nephritis that should be considered is an acute tubular one on a toxic basis. The history is entirely consistent with such a diagnosis. Of course, the most common toxic nephrosis is due to mercury poisoning. If one only had a history of mercury ingestion, the rest would be easy. The salivation, the bleeding gums, the abdominal pain and the very rapid course of the acute illness are quite in keeping with acute mercurial poisoning, but one is unable to make such a diagnosis without a history of mercury ingestion. One is intrigued by the occupational hazards, in this patient. He was exposed to carbon tetrachloride over a long period. I was unaware that this substance could produce renal damage until I looked it up yesterday and found that it can produce acute renal disease, particularly when taken by inhalation, as this patient took it. In the cases I was able to find, symptoms appeared within a few hours after exposure to high concentrations of carbon tetrachloride in a closed space. If the history is correct, this patient had not been exposed for a period of a week; it therefore seems unlikely that carbon tetrachloride could have played a role in the production of this disease. Furthermore, such a severe grade of anemia is unusual. That is also true of mercury poisoning. So far as amyl acetate goes, I have been unable to find reports of renal disease produced by it. What else the patient may have been exposed to, I do not know. Lead is not a constituent of most automobile paints today.

One other possibility should be mentioned in closing. It is conceivable that when the patient developed the upper respiratory infection he took some sulfapyridine or sulfathiazole, which could produce renal insufficiency in one of two ways: by plugging the renal tubules with acetylated crystals or by producing a severe hemolytic anemia and plugging up the tubules with hemoglobin deposits. That seems far-fetched, and I merely mention it in closing.

I should say that the most probable diagnosis is an acute glomerulonephritis, although I cannot exclude the possibility of some chronic process that went on for years. The chief cause of death was the acute process.

DR. JACOB LERMAN: Aside from the diagnosis, I am interested in the treatment. Why was calcium gluconate given in the presence of a high blood phosphorus?

DR. WILLIAM M. JEFFRIES: Calcium gluconate was given for two reasons: the administration of sodium citrate and Amphogel (the former to combat the acidosis and the latter to inhibit further phosphorus absorption) had failed to produce any noticeable improvement over the previous twenty-four hours; since the patient was failing rapidly, since his pulse was not obtainable, his cardiac rhythm was grossly irregular at a rather slow rate, and there were numerous muscular twitchings, we gave intramuscular caffeine to stimulate the heart and intravenous calcium gluconate to combat the muscular twitchings and low serum calcium and to control the cardiac irregularity, which might have been due to calcium deficiency. Fishberg<sup>2</sup> mentions that the tetaniform muscular twitchings and spasms of uremia can often be stopped almost instantaneously by the intravenous administration of calcium gluconate or chloride. In the case under discussion, we gave gluconate rather than chloride because of the presence of acidosis.

The temporary improvement following this treatment was quite striking. Within five minutes, the cardiac rhythm became regular, the pulse was stronger, the muscular twitchings stopped, and the patient responded to questioning. This condition lasted for about two hours, but then he again started failing rapidly, and in spite of further administration of caffeine, death occurred within a few minutes.

Of course whether the calcium helped restore the cardiac rhythm to normal is questionable, since the caffeine may have been responsible for this, but the twitchings were certainly helped, and we saw no evidence that the calcium had done any harm.

## CLINICAL DIAGNOSES

Glomerulonephritis (? acute, ? subacute, ? chronic).

Secondary anemia.

Uremia.

## DR. KRANES'S DIAGNOSES

Acute glomerular nephritis.

Uremia.

## ANATOMICAL DIAGNOSES

Nephritis, acute glomerular.

Pulmonary hemorrhage, bilateral, marked.

## PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The kidneys were slightly enlarged, weighing 350 gm. The surfaces were slightly pale and dotted with minute petechial hemorrhages. The histologic picture was characteristic of acute glomerulonephritis, with marked proliferation of the capsules and almost no scarring of the tufts. There was beginning lipoid degeneration of the tubules. It was a very acute lesion, consistent with three weeks' duration. The heart was rather small, weighing 250 gm. There was no pericarditis. There was a severe grade of hemorrhagic pulmonary edema with a histologic picture essentially like that of Case 28112,<sup>3</sup> in which it was much more diffuse, however. There was the same marked hemorrhage into the alveoli and the formation of plugs of fibrous tissue, even in this short period, which obliterated a great many of the minute branches of the bronchial tree.

DR. KRANES: Do you not think it is quite unusual to develop such a severe grade of anemia in so short a time?

DR. MALLORY: I can remember only one case of acute nephritis that had an anemia nearly so severe as this. This was in a boy of about ten in whom, as I remember, the red-cell count dropped to 2,000,000 in the course of a few weeks. The bone marrow in the present case was entirely nonspecific, — neither hypoplastic nor hyperplastic, — which is about what one would expect in a case of nephritis. There was nothing to suggest any underlying blood disease to explain the anemia, so that I am forced to conclude that it was probably on the basis of nephritis.

DR. KRANES: Did you find any reason to suspect that poisoning played a role?

DR. MALLORY: None whatever.

A PHYSICIAN: How do you account for the nocturia?

DR. MALLORY: Habit, I guess.

## CASE 28132

## PRESENTATION OF CASE

A twenty-five-year-old Greek housewife was admitted to the hospital because of increasing abdominal distention of several months' duration.

A year and a half before entry, she was operated on in another hospital because of "abdominal pains." She was told that "no tumor was found, but a cyst was removed." There was abatement of the pains. Some months after this operation, the patient developed transient jaundice, with clay-colored stools, pain in the right upper quadrant, nausea, vomiting and fever, apparently associated with intolerance for fatty foods. This attack cleared without medication or hospitalization. Nine months before entry, the patient experienced a similar episode. After this, she remained on a low-fat diet. Two and a half months before entry, she noted some distention of the abdomen, especially on the right side, without reappearance of any of her previous symptoms. After a month and a half, the distention became more generalized, and there was some constipation. The menses were regular until three months before entry, when there was slight dysmenorrhea, with an otherwise normal period. Two episodes of metrorrhagia occurred in the next month, and normal periods were then resumed. Finally, about a week before entry, the urine was "Coca-Cola colored" for three or four days. There was no weight loss during this illness.

The patient had been married several years without pregnancies. She lived in Greece until the age of thirteen. At the age of eleven or twelve, she had an undiagnosed sickness characterized by high fever. At that time, her diet included goat's milk, and she was in close association with sheep and other cattle. The family history was irrelevant.

On admission, the patient appeared thin faced, with slightly yellow skin and scleras. The heart and lungs seemed normal. The abdomen was swollen and tympanitic, with liver dullness extending several fingerbreadths below the costal margin. There was no evidence of peritoneal fluid.

The temperature was 99°F., the pulse 90, and the respirations 20. The blood pressure was 120 systolic, 88 diastolic.

Examination of the blood showed 1 red cell count of 3,700,000 with 93 gm hemoglobin, and 1 white cell count of 10,300 with 20 per cent polymorphonuclears, 23 per cent small lymphocytes, 2 per cent monocytes, 53 per cent eosinophils and 2 per cent basophils. No parasites were seen in the blood. The blood Hinton reaction was negative. The urine showed a + test for albumin and a sediment with 200 white blood cells, scattered and in occasional small clumps per high power field. Bile pigment was present in the urine in two out of three examinations. The stools showed no parasites or occult blood in six examinations.

A roentgenogram of the chest showed no positive evidence of disease. A roentgenogram of the abdomen showed a large dense mass filling the right side and extending down below the crest of the ilium. This mass seemed contiguous with the liver, and through it could be seen a normal kidney shadow. The spleen was not visualized.

On the second hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR HOWARD ULFELDER. In essence, we are presented with the case of a young married woman who was chronically ill and had noted increasing abdominal girth. Whether this represented an actual intra-abdominal mass we are not told. On physical examination, the abdomen was swollen and tympanitic, with liver dullness extending several fingerbreadths below the ribs. The x-ray report, however, was less noncommittal, stating that a dense mass filled the right side and seemed contiguous with the liver.

Let us assume that this was an intra-abdominal mass. What facts help localize the site of its origin? In the first place, we are told that the patient had an operation a year and a half previously. This could lead to endless conjecture, but I shall trouble with none of it. We do not know what the operation was or what was found or done. The patient had obviously been ill for a year and a half. Following this, she had symptoms that pointed definitely to the right upper quadrant. She had an attack of pain, with jaundice, vomiting, nausea and some fever, which was repeated nine months before entry. Presumably, she also had jaundice with the second attack. She was able to control the symptoms, however on diet alone, and it was not until two and a half months before entry, when she noticed gradual distention of the abdomen, that she became sufficiently preoccupied with her condition to come in and have something done about it. She had some jaundice on entry—chronic jaundice, I assume.

Are there any other facts that help us to find out what might cause a mass in or very near the biliary tree in a young married woman? We know that she was a Greek and had lived in Greece until she was thirteen. We note—in fact, it is specifically brought out—that she was in close association with cattle in her childhood. This, together with the marked eosinophilia, makes me believe that some parasitic infestation explains the disease, and the most likely one is the echinococcus. I therefore believe that the diagnosis in this young woman is hydatid cyst of the liver.

Can we localize it further? Have we the x-ray films?

DR TRACY B. MALLORY. We have the x-ray films but no radiologist to interpret them.

DR ULFELDER. We note that the diaphragm is not unduly elevated on the right side nor is there the tenting that is usually described in echinococcal cyst near the superior surface of the liver. The fact that the mass extends so far down into the abdomen,—it is described as reaching the iliac crest,—makes us believe that the mass is therefore in an unusual site, namely, the inferior aspect of the liver. Echinococcal cyst is said to occur most often in the right lobe, but in the right lobe more frequently near the superior interior aspect. It is conceivable that the great size of the mass is due to the fact that it occupies a somewhat more distensible structure, such as the gall bladder, and I toyed with the idea of hydatid cyst of the gall bladder. However, I believe that the diagnosis is hydatid cyst of the right lobe of the liver.

One final point the very high eosinophilia is said to be some indication that the cyst is actually draining. In other words, some form of allergic reaction is being produced in the body by the products of this parasitic infestation, and I therefore hazard the guess that the echinococcal cyst was so near the biliary tree that it actually spilled out daughter or granddaughter cysts into the common bile duct and hence into the gastrointestinal tract.

DR EDWARD B. BENEDICT. I peritoneoscoped the patient. The findings were as follows:

The entire upper abdomen was occupied by a firm comparatively smooth but uneven mass, parts of which were pearly grey in color, and parts of which were covered with numerous blood vessels. The lower border of which on the right side was smooth and rounded and extended about 4 cm below the umbilicus. On the left side it extended on a level with the umbilicus. The border of the liver on the left side was clearly seen being distinct from the mass and overlying it. It appeared sharp and normal, and its anterior surface showed no implant. On the right side, however it was impossible to distinguish the liver edge, the mass

appearing practically contiguous with it. The patient was so tender on the right side that examination was difficult. The gall bladder could not be seen owing to the mass. The right lobe of the liver appeared irregular and uneven. Some areas suggestive of metastatic disease were seen in the right lobe of the liver. There was a small amount of free bloody fluid in the pelvis. The patient was put in Trendelenburg position. A nodule, about 1 cm. in diameter and characteristic of metastatic disease, was seen in the cul-de-sac, surrounded by a half dozen small, pin-point implants suggestive of ovarian cancer. A biopsy was obtained from the large implant.

DR. MALLORY: Do you want to give your impression after peritoneoscopy?

DR. BENEDICT: My impression from the implant was that we were dealing with a malignant process.

DR. MALLORY: The specimen that Dr. Benedict obtained was sent to the laboratory, where we found that it consisted of fibrous tissue with many giant cells in it. We were unable to make any definite diagnosis and reported it as a granulomatous inflammatory process.

Do you want to add to or change your diagnosis, Dr. Ulfelder?

DR. ULFELDER: No; except that I might alter my opinion that it might have been spilling into the common duct and say instead that it was spilling into the free peritoneal cavity.

#### CLINICAL DIAGNOSIS

Echinococcal cyst?

#### DR. ULFELDER'S DIAGNOSIS

Echinococcal cyst.

#### ANATOMICAL DIAGNOSIS

Echinococcal cyst.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: A spilling into the peritoneal cavity had undoubtedly occurred. It was considered impossible to make a positive diagnosis without exploration, which was eventually done.

Dr. Leland S. McKittrick, who operated on this patient, found a very large cyst that had ruptured and was the site of a marked inflammatory process. However, it was quite possible to recognize it grossly, and later histologically, as an echinococcal cyst. It was much too large and too deeply embedded for removal, and he was forced to marsupialize it. The patient has had considerable relief of symptoms, but when she was discharged to a convalescent home she was still not what one could call well.

A PHYSICIAN: How about the gall bladder?

DR. MALLORY: It was normal.

MATERIAL for early publication should be received not later than noon on Friday.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston, Massachusetts.

## FINANCING THE WAR

We have accepted the challenge of the Axis forces. We will uphold our fight for freedom with all the resources of America. New England's production lines, like those the Nation over, are turning out more and more war matériel and equipment. Old factories are now making new tools of war. New armament lines are being built. This year, the total bill for the war effort will exceed \$60,000,000,000. Next year, it may be even higher. Victory is the goal—no matter how great the cost. And we as individuals must share the financial load.

We are paying higher taxes than ever before, but even a Victory Tax program falls far short of the amount required to meet the annual cost of war. A part of the money will be obtained from

banks and other lending agencies, but this does not make up the deficit. The Government must secure billions of dollars by borrowing directly from the people.

The Treasury Department offers United States Defense Savings bonds and stamps within the purchase range of all Americans. The largest bond costs \$10,000, the smallest stamp, 10 cents. This is the people's investment program—through which we, as individuals, invest our dollars in the war effort. At the same time, such investments build toward our own future security and can be drawn on in case of emergency.

There are three series of United States Defense Savings bonds. Series E bonds may be bought only by individuals and can be obtained at any post office and almost any bank. A bond of this series may be registered in the names of two persons or in the name of one, with a second listed as beneficiary. The smallest costs \$18.75 and pays \$25.00 at the end of ten years. Series F bonds are also appreciation bonds, but these can be purchased by associations and corporations, as well as by individuals. They cost 74 per cent of their face value, and the Government pays back the full face value at the end of the twelve-year maturity period. The smallest bond of this series costs \$18.50, and the largest, \$7400. The Series G bonds cost the same as their face value and pay interest semiannually at the rate of 2½ per cent. They mature in twelve years, and are issued in denominations from \$100 to \$10,000. Although bonds of Series F and G are issued only by Federal Reserve banks and the Treasury Department, most commercial banks handle applications for them.

Our forefathers fought to secure the freedoms of the American way of life. We, physicians of the present generation, must face the crisis of world conflict with the same unflinching spirit, whether this means service with combat troops, in base hospitals or among civilian communities. In addition, we must buy, and continue to buy, United States Defense Savings bonds and stamps. Our dollars must do their part in the forward march to Victory.

## THE INDUSTRIAL NURSE

INDUSTRIAL absenteeism due to accidents and disease accounts annually for tremendous losses in production, as well as financial losses to employers and workers. In reducing this drain, which eventually affects the whole community, the industrial nurse can serve in a vital role. Although in large plants the workers' health problems are supervised by a physician, the nurse working under him carries heavy responsibilities in any health program. She has valuable personal contact with the individual worker and knows just what his work is and, thus, his exposure to injurious substances or dangerous conditions. Such knowledge may be of great value to all concerned if a question of compensation arises. In her daily contact with the employees, she has an opportunity to detect symptoms or conditions that may be forerunners of more serious concern if allowed to go untreated—a respiratory disease, a dermatitis or cuts and abrasions that the worker may consider too unimportant to warrant medical care. Furthermore, she may be acquainted with the employee's home environment and with other outside factors that might affect his work or health. She is familiar with local social and health agencies that can be turned to for help in special problems. The well-trained, alert and tactful nurse can frequently supply the physician and employer with information about a worker that could be gained through no other medium. Actually, her position is that of liaison officer between the worker, the physician and the management.

If the nurse's responsibility in large plants is great, it is doubly so in small factories, where the great percentage of workers are to be found and where conditions may be very poor. Since a physician for such a plant is usually in attendance for only a few hours each week, he cannot be expected to know in detail the type of work performed by the workers, still less the workers themselves. Here the nurse is an invaluable source of information on special prevailing conditions and on such a matter as the introduction of new materials and processes entailing possible danger.

In a small factory, far more than in a large plant, the nurse must be a propagandist to employee and employer alike, and must work single-handed for simple hygienic measures, safety programs and the general principles of occupational health.

Morbidity rates for working men are higher—frequently far higher—than those for the general population, and it becomes obvious, now if never before, that the worker's health is of immediate concern to the Nation. The industrial nurse is as important in the present war as her sister with the Services, and every effort should be made to use her more extensively and to increase her responsibilities.

## MEDICAL EPONYM

### NEGRI BODIES

The results of the studies made by Adelchi Negri (1876-1912) as an assistant in Golgi's pathology laboratory at Pavia were first presented before the Società Medico-Chirurgica at Pavia, March 27, 1903. "Beitrag zum Studium der Aetiologie der Tollwuth [A Contribution to the Study of the Etiology of Rabies]" appeared in *Zeitschrift für Hygiene und Infektionskrankheiten* (43: 507-528, 1903). A portion of the translation follows:

The phenomenon to which I wish chiefly to direct attention is first the occurrence of a peculiar microorganism in the nervous system of rabid animals; everything leads us to believe that this is to be considered a protozoon. . . . Almost always, the favorite site for the microorganism is the Ammon's horn—always if the infection is subdural. In this region, especially in the larger nerve cells, the parasites are present in large numbers.

In a paper, "The Etiology of Rabies: The diagnosis of rabies on the basis of new discoveries," which was read before the Società Medico-Chirurgica at Pavia, July 14, 1903, and appeared in the above journal (44: 519-540, 1903) under the title, "Zur Aetiologie der Tollwuth: Die Diagnose der Tollwuth auf Grund der neuen Befunde," Negri made the following statement:

On the basis of my studies, I have concluded that this microorganism, which is found solely in the nerve cells of the rabid animals, is the specific exciting cause of rabies.

R. W. B.

## MASSACHUSETTS MEDICAL SOCIETY

## SPECIAL MEETING OF THE COUNCIL

A special meeting of the Council of the Massachusetts Medical Society will be held in John Wire Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, April 15, 1942, at 10:30 a.m., at the direction of the president, Dr. Frank R. Ober.

**Business** To receive and act upon the report of the Committee to Revise the By Laws.

MICHAEL A. TIGHE, MD, *Secretary*

Councilors are asked to sign one of the two attendance books before the meeting. The Cotting Luncheon will be served.

Dr. Ober requests that all councilors remain until the end of the meeting.

## COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: ECLAMPSIA, FOLLOWED BY FATAL CEREBRAL HEMORRHAGE

A twenty-three year-old primipara was first seen at the beginning of the seventh month of pregnancy. From then on, her care was excellent. When she was about eight and a half months pregnant, albuminuria and a blood pressure of 160 systolic, 90 diastolic developed, and she was hospitalized. The past history was irrelevant. Physical examination and the blood Wassermann reaction were negative. The pelvic measurements were normal. The usual treatment for toxemia was instituted, and the systolic blood pressure ranged from 140 to 160, with persistent albuminuria. Labor was not induced and did not begin until three weeks after the expected date. At the end of four and a half hours of labor, the patient was seized with convulsions and died undelivered. Autopsy revealed massive cerebral hemorrhage, with typical findings of eclampsia in the liver and the other viscera.

**Comment.** This patient was under hospital observation for three weeks, and it is very evident that at no time was she considered seriously ill. The record does not state just what the treatment for toxemia was. Many similar patients put on a skimmed milk diet of  $2\frac{1}{2}$  quarts daily, with nothing else to eat and with a recorded twenty-four hour urine output, show in a few days a lowered blood pressure, a diminution in edema, which this patient is said not to have had, and in the amount of albumin, and an increased twenty-four hour output. It is, of course, probable that had labor been induced when no improvement occurred, this fatality would have been prevented, and it is very possible that a vaginal examination when the patient was at estimated term would have revealed a cervix favorable for induction by rupture of the membranes.

Continued albuminuria and sustained blood pressure for three weeks can certainly do no good, and undoubtedly may cause kidney damage. Massive cerebral hemorrhage following so soon after convulsions is very unusual. The autopsy proved that this fatal complication may occur in a patient who has been showing only moderately increased hypertension. Hence, conservatism, which was the cause of this patient's death, can be carried too far.

## FAMILY NUTRITION AND DEFENSE\*

We all know that real defense is not only "for" the people but also "by" the people. The main job of all Americans is to build a strong America. For this, we depend on many important products like rubber and steel. However, it also takes men strong, husky ones, to work as well as to fight. Behind them stand millions of other Americans—large and small, old and young—willing to take an active part in this immense, undertaking.

Building men takes years. It is accomplished with such simple things as the right food, plenty of sleep, sunshine, fresh air, active work and play. Strength, stamina, nerve and grit come with robust health. The nation needs families where every member—from baby to grand parents—is in top notch buoyant health.

How about yourself and your family? Are their bodies well developed (not too thin, or too fat), their muscles firm (not flabby), their teeth sound (not decayed), their eyes bright (no dark circles), their skins clear (with good color), their hair glossy (not brittle), their postures alert and self-confident (not drooping), their appetites and digestions good (not finicky), their dispositions happy and fun-loving (not irritable and highstrung, or listless and seemingly lazy) and their endurance and vigor high?

Is there some point on which you could improve? Keeping fit is not always easy, but it is much cheaper and far simpler than getting back your pep after illness or overfatigue. It ensures greater physical vigor, sturdier nerves, clearer thinking, better resistance to disease and increased ability to turn out a good day's work—all very necessary for all of us, whether we are in the service, in industry, in school or at home.

America can become a nation of husky, well-nourished people, she has the food, the knowledge and the will to do it. It takes farmers, manufacturers, distributors, grocers—everyone.

We must know which foods are most economical to each member of the family, and how to buy these foods wisely and serve them tastefully.

We must also learn how to spend our money economically to get the greatest amount of protective foods—milk, eggs, fruit and vegetables—that our budget will allow, even though the costs of living go up.

Furthermore, we must care enough about the health and nutrition of ourselves and our families to change poor habits for good ones. We should learn to like all the foods that are on the A-1 list, those "priorities in nutrition." We should get to bed in time to get up in time for a good breakfast, instead of hustling off with just a swallow of coffee. We should plan our day's work and leisure so as to have time to relax and get a good night's sleep.

\*A "Green Lights to Health" broadcast given through Station W A B by Dr. M. Louise Drex on Saturday January 24 and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

Much of the defense program can be carried on only by experts. But here is a vital part that is up to each individual, and he alone decides how well it will be done. There are no medals, no glamour, no special citations for bravery, and it may seem humdrum. Remember, however, it is important. It does make a difference. Even your own personal efforts benefit not only you, but your family and community. Good nutrition puts more life in living. It depends on a few simple foods—for what we eat makes a great deal of difference in how we look and how energetic we feel. Choosing the most valuable foods means knowing which ones to buy, then being sure to eat your share of them at three good meals each day. (And a word about meals—take your time; don't rush—you'll enjoy them better and digest them more easily. Also, make mealtime a happy time, with no quarrels or disciplining.)

No matter whether you can afford to spend \$5.00 or \$6.00 apiece for food for each member of your family each week, or only \$2.50—all can be well fed. The pattern for choosing these foods is the same. It includes plenty of building material for strong bodies, minerals and vitamins for top-notch health, and calories for energy. Whether it costs a great deal or a little depends on whether your family has expensive tastes or enjoys the more economical foods, how thrifty you are in your shopping, and how good a cook and manager you prove to be.

The first and foremost need at any age is milk—three or four cups for children and two cups for adults—in one form or another, bottled or evaporated. Drink it plain, or as a milk shake, in cream soup, custard, pudding and ice cream and on cereal; or, perhaps, as cheese in a sandwich or salad, in macaroni or with gingerbread or crackers. The least expensive cheddar cheeses are as valuable as our former imported kinds. And evaporated milk mixed with an equal amount of water is equal to regular milk and costs less. It is fine for most recipes that call for milk.

Vegetables are a second need: one or more servings of white or sweet potato especially baked, boiled in the skin or mashed, and two servings of other vegetables, one of which is raw, if possible (it may be "second helping" on the same vegetable occasionally, if necessary). Green, leafy and bright-yellow ones are the more valuable, especially greens, carrots, tomatoes (fresh or canned), green peas and beans. Cooked, canned or frosted vegetables are about equal in food value so long as the juice in which they are cooked is used for soup, gravy or cocktails. Save food value by being sure your vegetables are not overcooked. Season them well and serve them in different ways to tempt your family.

Fruits are also essential, two servings, one of which is raw, especially oranges, grapefruit and berries. Fresh, canned and dried fruits are all good at any meal, or for snacks, and even in sandwiches, or as sweets in place of candy. It costs more to buy fruits and vegetables when they first appear in the market, but they are apt to be very reasonable only a few weeks later, so that it often pays to wait a little.

Use one egg a day, or at least three or four each week for each person. Serve at any meal, either plain or in foods like puddings, custards, salads and sandwiches. All eggs have the same food value, whether white or brown shell, local or Western: the color depends on the breed of hen, and freshness is often decided more by how cold the egg has been kept, than by how long it has been kept. Using cold storage eggs for cooking is good economy when your pocketbook is slim.

One daily serving of meat or fish is necessary. Dried

beans or peas, extra cheese, eggs, fish and peanut butter are substitutes if we cannot afford meat every day. Live (beef, pork, lamb or calf) stands at the head of the list. Eat it often. Most of the inexpensive meats and fish have as much food value as the costly ones. These meats may take more cooking, but often have better flavor. It is expensive to buy ready-cooked meats, unless your time is very precious. Many of the cheaper sausages and frankfurters, although low in price, have less real "meat value" than other low-cost meats.

Bread and cereals are vital. At least half the bread used should be dark,—rye, whole wheat, Graham and so forth,—and the rest made with enriched flour. Use dark cereals like oatmeal, rolled wheat, malted breakfast foods and shredded wheat, instead of white ones. Flakes and puffed kinds cost much more, when the number of servings in a package is considered.

Use butter on bread and vegetables as generously as your pocketbook allows. Vitamin A oleomargarine is almost as valuable and much cheaper than butter at present, but peanut butter is a good spread. Other fats are less necessary, since they supply only calories and no vitamins.

Regarding molasses and sweets, brown sugar gives you the most for your money and should be used often in place of white sugar. Simple desserts and sweets can be used in moderation and at the end of a meal, not to take its place. A sundae or a bar of candy is not equal to a meal, even if it satisfies hunger easily.

If your food money must be carefully stretched, remember that a fussy, finicky family is expensive to feed. Start them early to learn the fun of trying new things. Anyone can learn to like most foods if he tastes a little bit at first and tries it from time to time in weeks to come. Furthermore, eating out at restaurants and tea rooms and even extra snacks at the soda fountain run into money if they get to be a habit. If you entertain at home often,—either simply or in "bang-up" style,—your food budget will feel the strain unless you make allowances for this ahead of time.

Do not be satisfied to stop with the nutrition of your own family (although this is your first responsibility, of course). Help promote a good nutritional program for the whole community. All this takes courage and hard work. Such things are not easy to do in busy days like these. But they will be done by all who wish to build the defenses of America, with a virile civilian force as well as a strong fighting force, able to stand the gaff of everyday life, with power and assurance.

Write to the Massachusetts Department of Public Health at 73 Tremont Street, Boston, for more details if you are interested in nutrition and defense.

## DEATHS

BROWN—GEORGE A. BROWN, M.D., of Barre, died March 15. He was in his eighty-fifth year.

A native of Barre, Dr. Brown received his degree from Columbia University College of Physicians and Surgeons in 1883. He was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, two sons and two daughters.

CLARKE—INEZ L. CLARKE, M.D., of Cambridge, died recently.

Dr. Clarke received her degree from Tufts College Medical School in 1904. She was a member of the Massachusetts Medical Society and the American Medical Association.

**MUTTY**—**LAWRENCE T. MUTTY, M.D.**, of Wicahitum died February 25. He was in his thirty-seventh year. Born in Bangor, Maine, Dr. Mutty received his degree from Middlesex University School of Medicine in 1931. He was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, a son and a daughter.

**PETERS**—**ANDREW PETERS, M.D.**, of Longmeadow died January 8. He was in his fifty-second year. Born in Lake George, New York, Dr. Peters received his degree from Columbia University College of Physicians and Surgeons in 1914. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

His widow, two sons and a daughter survive him.

## WAR ACTIVITIES

### CIVILIAN DEFENSE

#### TEXTBOOK ON WAR GASES

*Protection against Gas*, a textbook on war gases to be used for instruction of public employees and volunteers enrolled in the various groups of civilian defense workers has been issued by the United States Office of Civilian Defense. The book was prepared by the War Department under the direction of the Chief of Chemical Warfare Service, United States Army, with suggestions from the National Technological Civil Protection Committee, a special advisory committee of engineers. The section, *First Aid Treatment of Gas Casualties*, was prepared with the assistance of the Medical Division of the Office of Civilian Defense.

Although war gases have been used only once in this war, so far as is known, it is essential that thorough preparation be made to deal with them. Several groups of state and local officials have already had training in the Civilian Defense School conducted by the Chemical Warfare Service at Edgewood Arsenal, Maryland. Graduates of this school are returning to their homes to instruct others in the identification of gases, measures for protection and methods of decontamination.

The 75-page manual contains descriptions of the principal gases, their effects and the first-aid measures to be used in the care of persons who have been subjected to gas attack. Methods of individual protection, which include the use of masks and the wearing of protective clothing, and methods of collective protection, such as use of gas-proof shelters and methods of decontamination, are described. There is a chapter on the protection of animals, especially horses and homing pigeons.

## NEW HAMPSHIRE MEDICAL SOCIETY

### DEATHS

**HINDS**—**WILLIAM H. HINDS, M.D.**, of Milford died March 10 in Wilton, where he had been ill for several weeks. He was born in Milford, July 22, 1867, the son of Dr. W. H. Hinds and Harriet M. Hinds. He graduated from Boston University School of Medicine in 1895, after which he was associated with his father in general practice in Milford until the latter's death.

Dr. Hinds was long prominent in the Masonic fraternity. For many years he was the school physician in Milford and Amherst. He was a member of the New Hampshire Medical Society and the American Medical Association.

**LA FRANCE**—**ALBERT J. LA FRANCE, M.D.**, of Laconia, died at home on March 12, after a long illness. He was in his seventy-first year.

He graduated from Bowdoin Medical School in 1896. He was on the original medical staff of the old Cottage Hospital at Laconia, and was a member of the Belknap County and New Hampshire societies, the American Medical Association and the American Ophthalmological Society.

Dr. LaFrance is survived by his widow, Mrs. Caroline J. LaFrance, a daughter, Mrs. Dorothy Brockington, of Buffalo, New York, a son, Dr. A. Philip LaFrance, of Laconia, and a brother, Edward LaFrance, of Gloucester, Massachusetts.

**WEBBER**—**NORMAN B. WEBBER, M.D.**, of Manchester, died suddenly on February 22. He was in his sixty-eighth year.

Dr. Webber graduated from University of Vermont, College of Medicine in 1903. He was a member of the New Hampshire Medical Society.

## MISCELLANY

### ILLUMINATION OF TUBERCULOSIS IN CIVILIANS AND IN MEMBERS OF THE ARMED FORCES

We are all in it, said the President the day after bombs dropped on Pearl Harbor. "Every single man, woman and child is a partner in the most tremendous undertaking of our American history. The following abstracts, derived from three papers presented at the thirty-seventh annual meeting of the National Tuberculosis Association, indicate the important role played by the medical profession in the victory effort."

#### CIVILIAN HEALTH AS A FACTOR IN NATIONAL DEFENSE

(Miller, K. E. *Am Rev Tuberc* 44: 637-650, 1941)

The stem from which all manpower springs is the civilian population. The strength of the branch can be no greater than that of the stem. How strong is the stem? The findings of the National Health Survey made in 1935-36 afford some measure.

It may be estimated that 70,000,000 sick persons each year lose over one billion days from work or customary activities, and that the cost of illness and premature death in this country amounts annually to about \$10,000,000,000. The decline in the total death rate has been accomplished largely by lifesaving in infancy and childhood, which allows larger numbers to reach the age of maturity. Consequently, there is an upward trend in diseases of middle and old age, such as heart disease, nephritis, cancer and diabetes.

More than half of all tuberculosis deaths occur in the age group fifteen to forty-five. This heavy loss comes approximately within the age limits for military service. And for every death, there are approximately 10 clinical cases of illness from tuberculosis.

Disabling conditions among children, dental defects, venereal diseases, pneumonia, malaria and accidents are other leading causes of death and disability. The mental hospitals contain about 500,000 inmates, with 50,000 on parole, and about 75,000 patients are in institutions for the feeble-minded and epileptic.

Studies of the economic status of families shows a direct correlation of sickness with low income. Disability due to illness was nearly two and a half times as great among persons in the income group under \$1200 (an

nually) as in the group above \$3000. When it is recalled that the low-income groups constitute a large proportion of those who are employed in industries more or less directly connected with national defense, the losses sustained as a result of unnecessary illness may be regarded in the light of domestic sabotage.

#### PULMONARY TUBERCULOSIS, ITS EXCLUSION FROM THE NAVY

(Duncan, R. E. *Am. Rev. Tuberc.* 44:651-657, 1941)

Compactness of living spaces aboard a naval vessel is a necessity. Advances in ship construction from the standpoint of ventilation and sanitation in general have been made, but men living aboard are still somewhat crowded. Under such conditions, an open case of tuberculosis is a real menace. Medical officers are on the alert, but the average sailor likes to think of himself as rugged and hardy and will not, as a rule, report to the sick bay unless he really feels sick.

No applicant showing any degree of adult type tuberculosis is acceptable. Men in the service who develop tuberculosis are retired and are not subject to recall to active duty, even with long-standing arrest and minimal lesions.

The Medical Department of the Navy has recognized that at least 30 to 40 per cent of minimal cases will be missed by well-trained phthisiologists, depending on the conventional methods of physical examination alone. The criterion to be used in weeding out tuberculosis must be radiography. What form of radiography might be most practical for the Navy has been studied for some years. After the advantages and disadvantages of the several methods now available were considered, fluorography with the 35-mm. film was found to be the best solution to the problem.

Speed is an important factor during a period of mobilization. A smoothly working team can easily turn out from 100 to 150 films per hour. At present, examinations are not exceeding the rate of 80 per hour, in the interest of careful posturing and some regard for the life of the x-ray tube.

However, these miniature films are not used for fine diagnostic work, but serve merely as a sieve to screen out the abnormal from the normal chest. In any case showing a lesion or even a questionable area, a standard 14-by-17-inch celluloid film is made for confirmation and accurate diagnosis. The method has definitely passed the experimental stage, and it is ideal for mass thoracic-survey work. At one training station, photofluoroscopic examinations of 5171 recruits were made. These men had already passed two stringent physical examinations. Yet, of these recruits, 15 men showing soft infiltration in the lungs and 3 with multiple calcification and fibrosis of a disqualifying extent were transferred to the hospital for further study and disposition.

The incidence of tuberculosis in the Navy is not high during normal times and has been steadily declining.

#### TUBERCULOSIS IN THE ARMY

(Pollock, W. C. *Am. Rev. Tuberc.* 44:658-674, 1941)

This paper, presented May 8, 1941, was largely a criticism of certain faults in the program for detecting tuberculosis among inductees. By December, 1941, however, the author was able to add to the summary the following:

"Since presenting this paper, the Army Tuberculosis Survey has been improved. Practically all inductees are now being x-rayed prior to induction into the Army.

Tuberculous inductees are not enrolled. It is considered that the Army now has an excellent program of tuberculosis survey."

The mobilization survey of 1941-45 will be the greatest case-finding effort ever carried out in this country. Its purpose will be to detect chest diseases that would incapacitate the inductee for active military service; to detect diseases that may be so aggravated by military service that the inductee becomes incapacitated for military service; to detect, especially, pulmonary tuberculosis with subsequent isolation of the patient from contact with young noninfected persons; to report all tuberculous inductees to proper state health authorities.

The demobilization survey will consist of the routine general physical examination followed by an x-ray examination of the chest. Thus far, the x-ray examination has been made shortly after induction. and for this purpose the 14-by-17-inch film has been mostly used. At present and in the future, the x-ray survey will be made chiefly by use of fluorograms, with 4-by-5-inch film. Two films are made, one of which is sent to the War Department for permanent record. On demobilization two additional fluorographic films will be made, with like disposition of the films.

The chief fault of this plan, namely, that the x-ray film of the chest is usually not made until after induction has been corrected.

Another fault is that inductees may be discharged on their own care unless in need of hospitalization. Medical officers will tend to err on the side of safety and many tuberculous inductees will be sent to Army hospitals who should have been discharged to their homes. When viewed from the standpoint of epidemiology, however, this may have the advantage of bringing a large number of cases under control and thus decreasing tuberculosis in the community.

Mobilization regulations allow the induction of a person with reinfection tuberculosis when the process is minimal in extent and arrested. This can be done when, in the opinion of the examiner, the lesion is not likely to become reactivated under the conditions of military service. This is a dangerous exception, for many experts are able neither to estimate properly the true potentialities of a fibrous, tuberculous process nor the "condition of military service."

Through this contemplated survey, thousands of new cases will be detected. It is essential to plan for their care. No official estimate of the number that will be discovered has yet been made, but the author hazards the guess that between 1941 and 1945, a grand total of 88,000 cases will be detected.—Reprinted from *Tuberculosis Abstracts*, March, 1942.

#### NOTES

Dr. Arlie V. Bock, Henry K. Oliver Professor of Hygiene, and David B. Dill, director of the Fatigue Laboratory, Harvard University, have been chosen to deliver the James M. Anders Lecture before the College of Physicians of Philadelphia on April 1.

The School of Medicine of Middlesex University has recently announced that it has adopted the three-year accelerated educational program. The present school year will end on June 15, and the new school year (1942-1943) will start on July 1, instead of in September. Steadily rising costs of operation have necessitated the raising of the annual tuition fee to \$450.00, payable in three installments.

## OPTIMAL DOSAGE AND THE RECIPROCAL RELATION OF DESOXYCORTICOSTERONE ACETATE AND SODIUM IN ADDISON'S DISEASE\*

THOMAS H. MCGAVACK, M.D.†

NEW YORK CITY

**D**ESOXYCORTICOSTERONE is a readily available ketosteroid of the adrenal cortex and has greater life-maintaining qualities than any chemically pure constituent isolated to date.<sup>1-5</sup> Nevertheless, such extreme practical difficulties have been encountered in its clinical application in cases of Addison's disease<sup>6-9</sup> as to lead to its condemnation in certain quarters.<sup>6,9</sup>

The drug affords satisfactory replacement therapy for adrenocortical deficiency so far as the vital and sodium-regulating factors are concerned. Moreover, it enables the animal to store and use carbohydrate food and exogenous protein satisfactorily, but fails to restore the ability of the organism to produce sugar and glycogen from endogenous protein and fat. If properly used, it enables the patient with Addison's disease to resume his usual daily activities.

The dangers in the application of desoxycorticosterone have been centered around its predominant effect on electrolyte metabolism—with particular reference to sodium. The early failure to understand clearly the extent of this action has been responsible for the untoward reactions observed. Wholesale condemnation of the drug on this basis alone seems presumptuous, since very few useful additions to the therapeutic armamentarium of the physician have been without limitations.

It has been shown that sodium and desoxycorticosterone exert a similar beneficial action in the adrenalectomized animal, and that although salt in sufficient quantity in such animals maintains life, it does not afford the same vitality as a combination of the two agents.<sup>10,11</sup> The ability of desoxycorticosterone to prevent salt loss and to correct faulty potassium exchange in the subject with

adrenal insufficiency is its best known action. At the same time, it is the one that has led to most of the complications.

During the last two and a half years, 6 cases of Addison's disease have been treated with desoxycorticosterone acetate, together with regulation of the sodium and potassium intake. From observation on this group of patients, two conclusions concerning the efficacy and safety of desoxycorticosterone as a therapeutic agent can be drawn: the patient with Addison's disease can be satisfactorily maintained in good health by the judicious use of desoxycorticosterone acetate and the simultaneous regulation of sodium and potassium intake; and within certain limits, a reciprocal relation exists between the amount of sodium to be ingested and the dose of desoxycorticosterone acetate necessary to maintain the subject in good condition.

The criteria of "maintenance in good condition" include a sense of well-being on the part of the patient, a slow, steady gain in weight or a maintenance of normal weight once attained, a return of blood pressure to normal and its fixation there, a gradually rising cardiothoracic ratio,—not to be allowed to exceed 0.50, and preferably maintained around 0.46,—normal values for sodium and potassium in the blood serum and urine, and improvement toward normal in the configuration of glucose-tolerance curves.

The repeated determination of the blood sodium and potassium values and of the glucose-tolerance curve is comparatively difficult for the average practitioner and often barred by the expense entailed to the patient. Such determinations are not essential, so long as the other reasonably simple procedures are carried out. Rapidly rising cardiothoracic ratios should be avoided. This point warrants some emphasis. In no case have I seen hypertension or edema whose onset was not pre-

\*From the Department of Medicine, New York Medical College, and the Medical Service, Flower and Fifth Avenue Hospitals and Metropolitan Hospital.

†Associate professor of medicine, New York Physician, Flower and Fifth Avenue Hospitals and Metropolitan Hospital.

ratio between the transverse diameter of the heart and the transverse diameter of the chest. Since these patients almost invariably need a roentgenogram of the heart and lungs as a part of the initial diagnostic survey, subsequent changes can be compared to the size of the heart as obtained in this first study. If necessary, these changes may

signs of overdosage, in no case resulting seriously.

Using the criteria mentioned, it has been possible to bring about in these 6 patients with Addison's disease a state of stabilization sufficiently good to permit each to return to his previous walk in life. Particular care has been taken to regulate sodium intake and desoxycorticosterone dosage re-

FIGURE 1. Clinical Results in 6 Cases of Addison's Disease following the Use of Forty-seven Different Ratios for the Daily Intake of Sodium and Desoxycorticosterone Acetate.

The numerals indicate the number of cases represented by a given point.

be charted in the office even less expensively by orthodiascopy.

Signs of overdosage with desoxycorticosterone acetate include a sudden gain in weight, hypertension, a cardi thoracic ratio above 0.50, edema of any part of the body (late manifestation) and a definite feeling of malaise not unlike that prior to the administration of any treatment for the disease. Indeed, in the early handling of patients by the use of desoxycorticosterone acetate, these symptoms were considered an aggravation of the state of adrenal insufficiency, and more of the drug was administered.<sup>9</sup> Manifestations may vary from patient to patient, but the extreme sense of fatigue and weakness that is so characteristic of the Addisonian state itself is common to all patients. On three occasions, I have observed

ciprocally, since failure to recognize the dangers of too much of one in relation to the other appears to have caused the difficulties seen in the management of the disease. To analyze the results, each change of sodium administered or desoxycorticosterone used has been charted in relation to the other, and the state of health of the patient carefully checked while on each such variation of his regime (Fig. 1).

The amount of sodium and desoxycorticosterone acetate given daily was recorded for each of the 47 trial periods. The patient remained on each of the changes made for not less than six weeks, except in those cases in which signs of overdosage became apparent, or in those in which signs of insufficiency were severe before such a period was completed. As judged by the criteria already mentioned, the

patients were in hormonal balance in 28 of the trial periods, in insufficiency in 16, and subject to complications in 3. If an attempt is made to pass a curve through a majority of the plotted points in which a balanced ratio between sodium and desoxycorticosterone exists, the pattern of such a curve clearly becomes that of a hyperbola,  $Na = k \div D$ , where  $Na$  represents the daily intake of sodium in grams,  $D$  the daily dose of desoxycorticosterone acetate in milligrams, and  $k$  the constant. When substitutions were made in this formula from figures used in ascertaining the optimum dosage in a number of cases,  $k$  equaled 45 in 14 periods and 37.5 in 4, and in the remaining 10 periods, lay between 30 and 37.5 in 2, between 37.5 and 45 in 2, and between 45 and 55 in 6. In other words, a hyperbola with the formula,  $Na$  (gm.)  $= 45 \div D$  (mg.), passes through 14 of 28, or 50 per cent, of all the trials during which the patient was shown to be in a satisfactory state of balance; the next greatest frequency is given by the formula,  $Na$  (gm.)  $= 37.5 \div D$  (mg.), which passes through 4 of 28, or 14 per cent, of the points of optimal dosage plotted. No complications arose when ratios lay close to those indicated by either of these curves or by points between them. The area between them might be spoken of as the "zone of safety" for the selected dosage of sodium and desoxycorticosterone acetate. My experience suggests that dosages should lie closer to the first-mentioned curve with a constant of 45 (heavier line). It seems obvious, however, that no predetermined ratio for sodium and potassium is satisfactory in all cases, since the degree of adrenal insufficiency varies from patient to patient. Nevertheless, from present evidence, this variation takes place over a rather narrow range of equivalents, in contrast, for example, to the wide variation of insulin dosage necessary in the treatment of patients with diabetes mellitus. Such a difference can possibly be explained on the basis that thus far it has been impossible to produce "grades" of adrenal insufficiency experimentally. The operator either removes so much of the gland that the animal dies, or by leaving even the slightest fraction more, enables the animal to survive, apparently in the best of health.

As with any other biologic relation capable of expression in a hyperbolic curve, limits of applicability are in evidence. My observations suggest that patients do best when the daily intake of sodium is varied between 2.3 and 9.0 gm., and that of desoxycorticosterone acetate from 5 to 20 mg. (Fig. 1). Patients on a higher quantum of sodium with concomitantly less desoxycorticosterone had less endurance and, in general, felt "less fit" than when the ratios noted above were observed. Moreover, higher dosages of desoxycorticosterone

were associated with more nearly normal glucose-tolerance curves,<sup>12</sup> although carbohydrate metabolism could not be regarded as completely normal in any case. The highest doses of desoxycorticosterone acetate—20 to 33 mg.—have been quite satisfactory from the patients' point of view. The majority state that they "feel fine." Despite the concomitantly low salt intake, however, blood pressures tend to remain at upper normal levels, and it has been suggested that some storage of sodium, with possible "packing" of the cells, may be taking place.<sup>13,14</sup> It seems logical and practical to make the range of dosage of desoxycorticosterone conform to the normal range of sodium intake (3 to 6 gm.) as indicated by the interrupted line in Figure 1. If this is done, it appears that from 7.5 to 15.0 mg. of desoxycorticosterone acetate can be given daily over relatively long periods. I had originally gained the impression that such a dose was too high for continued use without careful supervision of the patient; this may yet be proved true, for it is quite possible for some regeneration of cortical tissue to take place, or for aberrant tissue to initiate functional activity. If the curve of the lower constant (37.5) is used, this dosage in the range mentioned lies between 6.3 and 12.5 mg. daily. I consider this a perfectly safe amount in any patient with proved Addison's disease.

Previously stabilized patients in whom the product of sodium in grams and desoxycorticosterone in milligrams was changed to 15 or less (6 trials) quickly developed obvious signs of adrenal insufficiency, with a loss of weight, a fall in blood pressure, cardiothoracic ratio and blood serum sodium, and a return of progressive weakness. Such low values should be completely avoided when one plans the therapeutic regime of the patient with Addison's disease.

Three patients showed signs of toxicity from overtreatment. Two of these are as follows:

CASE 1. H. L. had been receiving 10.7 gm. of sodium and 10 mg. of desoxycorticosterone acetate daily for 9 days, when she developed swelling of the ankles, puffiness about the eyes, slight dyspnea and increased weakness. There was no pulmonary edema, but the heart was markedly enlarged, with a cardiothoracic ratio of 0.58, a heart volume of 693.0 cc. per square meter of body surface, and a blood volume of 5963 cc. (theoretic normal, 4466 cc.). Sixteen days previously, these values had been 0.41, 328.8 cc. and 3507 cc., respectively. This patient was later given 15 mg. of desoxycorticosterone acetate daily when the sodium intake was limited to 3 gm. For 6 months, there were no untoward effects. It is obvious, therefore, that the toxic reaction was not a factor of the drug alone, but was produced by the interaction of the steroid with available sodium.

CASE 2. J. P., a 60-year-old man, was in an extremely emaciated condition, bordering on crisis, when first coming under treatment. For 6 months, he had suffered from a continuous diarrhea, with severe, intermittent,

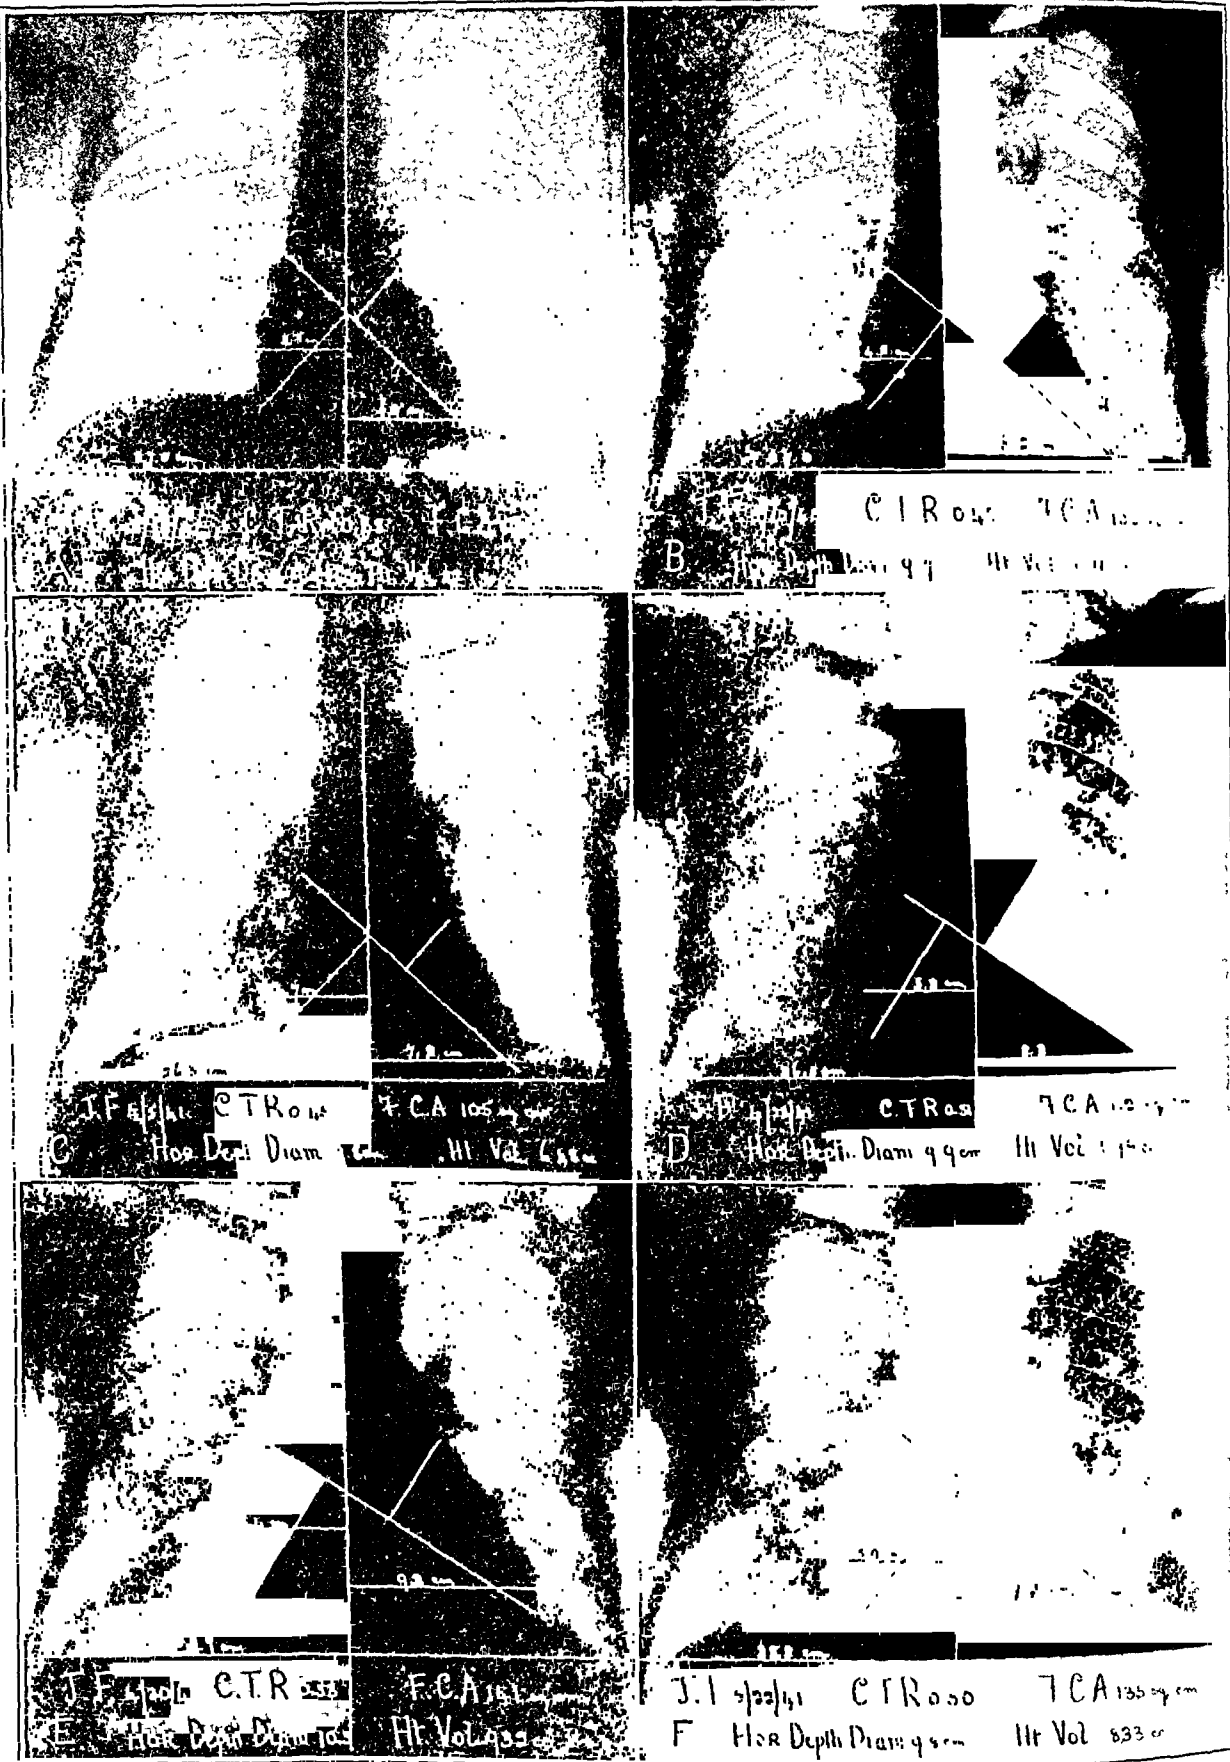

FIGURE 2. Serial Variations in Teleroentgenographic Shadows in Case 2 while the Patient was on a Constant Intake of Sodium and a Changing Dosage of Desoxycorticosterone Acetate.

crampy, upper abdominal pain. Throughout treatment, he was maintained on a daily dosage of 3 gm. of sodium. It was necessary to give him 25 mg. of desoxycorticosterone acetate daily before the abdominal symptoms were completely controlled, although he had shown improvement in his general condition when the amount of steroid was 15 mg. He showed no signs of toxicity from 25 mg daily until the end of 2½ weeks, when the blood pressure was 148/84 (normal for 60 years of age) and other factors, such as a sense of well-being, weight and serum electrolytes, were within normal limits, but the cardiothoracic ratio had increased from 0.45 to 0.51 (Fig. 2 and Table 1).

One week after changing to 1.5 gm. of sodium and 30 mg. of desoxycorticosterone acetate daily, the patient developed mild occipital headaches and slight ankle edema. The weight, blood pressure and cardiothoracic ratio, which had previously been 58.6 kg, 140/72 and 0.42, respectively, became 59.0 kg., 164/120 and 0.48, respectively. Subjectively, the only symptom was headache, which never required medication. Within a week, the edema subsided, the headaches disappeared, and the blood pressure returned to within normal limits (138/85). The patient was maintained on the same regime for an additional 3 weeks, and continued to gain in weight and strength. The cardio-

TABLE 1. *Changes in Cardiothoracic Ratio in Case 2.*

X-RAY FILM (FIG. 2)	DATE	CARDIO-THORACIC RATIO	BLOOD PRESSURE mm Hg.	DESOXYCORTICOSTERONE ACETATE mg.	COMMENT
A	1/23/41	0.38	70/50	0	Cortical insufficiency
B	3/12/41	0.45	95/65	5 (1 week) 10 (2 weeks)	
C	4/5/41	0.45	100/70	20 (2 weeks)	Good clinical condition
D	4/23/41	0.51	116/72	25 (2½ weeks)	"Feels fine," and gaining rapidly, note high cardiothoracic ratio, sodium desoxycorticosterone product high at 75
E	4/30/41	0.53	148/84	25 (1 week)	Went into cardiac failure on this date; note the normal blood pressure but high cardiothoracic ratio
F	5/22/41	0.50	132/80	15 (3 weeks)	Lung fields clearing, cardiothoracic ratio decreasing, sodium desoxycorticosterone product normal at 45.

In spite of the rise of the ratio above 0.50, it was decided to continue the previous regime, to complete special studies reported elsewhere.<sup>12</sup> One week later, the blood pressure had risen to 148/84, the cardiothoracic ratio to 0.53, and the patient suddenly developed ankle and pulmonary edema, breathlessness, dilatation of the heart and weakness.

The second case demonstrates the fact that the cardiothoracic ratio is one of the earliest and most sensitive indicators of overdosage. I still believe that ratios should be maintained in the neighborhood of 0.46,<sup>15</sup> to avoid any possible danger of toxic manifestations, although outspoken symptoms have not been seen with any ratios below 0.51. This is the only case in which frank cardiac failure occurred. Such a disturbance appeared only after three and a half weeks on a drug and sodium ratio nearly twice that which would have been indicated by the "dosage curves" of Figure 1. This certainly suggests that the drug can be used without danger in the average case, if proper attention is paid to simple rules of administration.

The third reaction observed, which was a most interesting and yet a very mild one, disappeared without any change in treatment.

CASE 3. E. M., a 24-year-old man, for over a year was comfortably stabilized on a daily sodium intake of 6 gm. and a sufficient number of pellets by implantation to yield 25 mg. of hormone daily.\*

\*By trial-and error removals and weighings in this and 3 other cases, it was estimated that each 150 mg. pellet of desoxycorticosterone acetate from the source available (Schering Corporation) gives a daily absorption of 1 mg. Each milligram so absorbed appears to equal 3 mg. of material when injected in oily suspension. It is essential to know the source of pellets for implantation, since the shapes, sizes and hardness alter the rate of absorption and vary considerably with different manufacturers.

thoracic ratio was stabilized at 0.46, the serum sodium remained within normal limits, and, moreover, the absorption and utilization of glucose, as indicated by the oral glucose-tolerance curves, improved materially.

This is the only case in which a reaction occurred when the product of the daily ration of sodium in grams and desoxycorticosterone acetate in milligrams was 45 or less. The fact that the reaction disappeared spontaneously is not explained. It has been suggested that with such high doses of hormone—despite the concomitantly very low ingestion of salt—a packing of sodium into the interstitial spaces and into the cells themselves must occur.<sup>13, 14</sup> It therefore seems unwise in the present state of knowledge to utilize the proportions suggested by the extreme right end of the hyperbolic curve for very long periods.

#### SUMMARY

Forty-seven variations in the ratios of sodium and desoxycorticosterone acetate used in the management of 6 patients with Addison's disease were plotted with respect to each other.

In 28 trial periods, the patient was in hormonal balance, that is, in good clinical condition with normal values for weight, blood pressure, cardiothoracic ratio and serum electrolytes. In 3, there were signs of toxicity from overdosage, and in the remaining 17 there was clinical and laboratory evidence of adrenal insufficiency.

All the ratios representing patients in "good clinical condition" have been shown to lie on, near or between the portions of two hyperbolic curves, whose constants are 37.5 and 45 respec-

tively. Fourteen actually lay on the latter curve. The area between these curves may be spoken of as the "zone of safe dosage."

As a general rule, patients felt best and showed most nearly normal carbohydrate utilization on dosages of hormone ranging between 10 and 20 mg. daily, with corresponding values for sodium, whereas larger doses did not augment these effects materially. Patients receiving less than 5 mg. of hormone daily, and concomitantly more than 9 mg. of sodium daily, did not "feel fit," despite the maintenance of weight, blood pressure and serum electrolytes within a normal range of values.

### CONCLUSION

Patients with Addison's disease can be safely and satisfactorily treated with desoxycorticosterone acetate, provided that attention is paid not only to the usual criteria of well-being, but also to the regulation of the dosage of drug and intake of sodium in a reciprocal manner. Values for these two variables represented by points lying on or between portions of hyperbolic curves in which the constants are 37.5 and 45, respectively, have been found to yield satisfactory results in clinical cases of insufficiency of the adrenal cortex.

## AN IMPORTANT ETIOLOGIC FACTOR IN SO-CALLED "FOOT STRAIN"\*

ROBERT B. OSGOOD, M.D.†

BOSTON

ROBERT Louis Stevenson once said that after the old man has listened to the young man, the old man usually remarks, "Well, my boy, I thought that at your age." We older men will do well if we constantly remember Stevenson's comment to the effect that the old man's remark suggests that "the young man was probably right." Nevertheless, if as we grow older we can manage to keep a reasonably open mind and do not ride our hobbyhorses too hard, experience may be the worthy teacher that it is proverbially said to be. Consequently, I have the temerity to call attention to what I believe to be an important and somewhat neglected etiologic factor in foot strain or, as the condition is still erroneously called, "flat foot." The subject is hackneyed, but the sufferers from foot strain are still many.

May I refresh your minds as to the essential rudimentary anatomy of bipedal symptomless weight bearing?

Good posture, which conforms to the lines of gravity, will be taken for granted. The normal lines of weight bearing, transmitted as they are

FIGURE 1. Medial Aspect of the Bones of the Foot.

through the tibias, fall considerably to the inner or medial sides of the feet. So far as the bony anatomy of the lower leg and foot is concerned,

\*Read at the annual meeting of the New England Surgical Society, Hanover, New Hampshire, September 6, 1941.

†John Ball and Buckminster Brown Professor of Orthopaedic Surgery Emeritus, Harvard Medical School.

the lines of weight bearing tend to depress the feet on their medial aspects. What resists this straining force? Neither of the two bony arches of the foot—the longitudinal arch from the os

FIGURE 2. Lateral Aspect of the Bones of the Foot

calcis to the metatarsal heads and the anterior transverse arch formed by the heads of the metatarsal bones—has any keystone worthy of the name (Figs. 1 and 2). One, therefore, cannot depend on the bony configuration to resist this deforming, inward, sagging force. The weight is transmitted through the tibia to the astragalus at the ankle joint, and thence to the os calcis and the ground. The main joint between the astragalus and the os calcis is a shallow ball-and-socket joint, but the projection of the sustentaculum tali on the inner side of the os calcis offers a prop that would keep the astragalus from rolling medially or inwardly, provided the os calcis could retain the vertical plane. The os calcis is held in this vertical plane by the strong posterior calcaneo-scapoid and the tibioastragaloid or deltoid ligaments, the plantar ligaments and the capsules of the joints of the tarsal bones (Fig. 3). These

FIGURE 3. Ligaments Supporting the Os Calcis.

ligamentous structures are only passive supports and will stretch and weaken if a continuous force such as faulty weight bearing is active

By far the major factors that maintain proper weight-bearing lines in the feet are the muscles of the lower leg, which have their insertions in the feet, and to a lesser extent, the intrinsic muscles of the feet themselves. These are active, not passive, supports.

Duchenne<sup>1</sup> (1806-1875), that brilliant son of a Boulogne sea captain, invented an electric apparatus that determined the exact function and comparative strength of the muscles by stimulating their contraction. It had previously been necessary to make skin incisions and to stimulate the muscles by actual contact. His invention of moist electrodes over the muscle bellies did away with

FIGURE 4. Posterior View of the Muscles of the Lower Leg.

the necessity for surgery and enormously simplified the study of muscle function. One of the many increments of knowledge that this careful pioneer added came from his study of the muscles of the lower extremities in relation to weight bearing. He reached the conclusion that faulty weight bearing and foot strain were most commonly caused by a faulty balance between the group of muscles that inverted the foot and elevated the arches and the group whose contraction tended to evert the foot and depress the arches. His conclusion was sound, but few seem to have applied it to the relief of foot strain.

Figures 4 and 5 illustrate the principal muscles of these two synergistic but more or less antagonistic groups. The first group may be called the inverters or the maintainers of symptomless weight bearing; if the second—the everters—overbalances the inverters, foot strain usually results.

Many years ago, I was interested in several patients who consulted me because they had been rejected for the fire and police departments of "flat feet." They protested

had any symptoms from their pedal extremities, and a few of them boasted of their prowess as long-distance walkers and of the prizes they had

inverters or adductors and the everters or abductors. A simple and fairly foolproof apparatus was devised, which is illustrated by Figure 6.

The late Dr. Arthur T. Legg was then in charge of the large foot clinic at the Carney Hospital, and I was working in the equally large clinic of the Massachusetts General Hospital. Dr. Legg, always the kindest of men, did the testing at the Carney Hospital. We agreed to test the comparative strength of these two groups of muscles in four different types of feet: symptomless feet, which exhibited, in shoe wear, and in walking, normal weight-bearing lines; feet that were symptomless but in which a slight sag toward the inner side (what is usually called pronation) was exhibited; feet that tired easily and were usually tender to pressure beneath the calcaneoscaphoid ligaments and frequently exhibited calluses beneath the anterior arches—this group showed still more faulty lines of weight bearing than those of the second type, that is, more exaggerated pronation; and painful feet, usually but by no means always flat, which were tender to plantar pressure and flexible to passive motion, and were covered by shoes that bulged on their inner sides—these are commonly called “acute flat feet,” and their possessors seem to have lost the joy of life.

Dr. Legg and I agreed not to discuss or compare our findings until we had tested a sufficient number of feet to give some reliability to our statistics. When a total of a hundred and twenty tests had been made, including all the four classifications, we compared our figures. To our surprise and satisfaction, we discovered that the aver-

won in track sports. When they stood, their feet were certainly flat, but when they walked or ran their weight-bearing lines were perfect. Apparently, the fire and police departments had rejected

FIGURE 5. Anterior View of the Muscles of the Lower Leg.

FIGURE 6. Apparatus for Testing the Strength of the Adductors and Abductors of the Foot.

excellent men because when they stood their feet were flat. I determined, therefore, in 1907, to make a study of the comparative strength in pounds pull of the two antagonistic groups of the

ages that we had independently computed in the two different clinics were well-nigh identical. The exact fractional percentages of the different groups were published in 1908.<sup>2</sup>

In the first group, which one may call the symptomless normal feet, the inverters of the foot, acting as protectors of the arches, were stronger than the everters or depressors of the arches in the ratio of approximately 5 pounds pull of the inverting protectors to 4 pounds pull of the everting depressors.

In the second group, also symptomless but exhibiting slight pronation, the pull of the two groups of muscles was approximately equal, but slightly in favor of the everters or depressors of the arches.

In the third group, that of patients with more pronated feet seeking advice because of symptoms of foot strain, the pounds pull of the everters or depressors of the arches was definitely stronger than that of the inverters or protectors of the arches.

In the fourth group, comprising the "acute flat feet," the ratio of the pounds pull of the inverters to that of the everters was approximately 4:5; in other words, the reverse of the ratio that existed in the test of normal symptomless feet.

On the basis of these tests, it seemed worth while to determine in some impartial manner the possible preventive and therapeutic implications of the findings. An opportunity to examine by means of these muscle tests the feet of probationer nurses was afforded by the superintendent of the School of Nurses at the Massachusetts General Hospital. These young women were taking up an occupation that required longer hours of standing and walking on harder surfaces than the majority of them had experienced. I was informed that in the rather large classes of probationers there had previously been a rough average of one nurse a week obliged to be off duty because of foot strain. For a year, I was allowed to examine and test in the manner I have described the feet of all the probationers soon after they took up their new duties, and to advise them in accordance with the findings of the test. If my memory is honest, no nurse who had followed the advice given on the basis of the test was laid up for foot strain during the year. Moreover, only one of the probationers who exhibited a normal balance test at her original examination reported for foot strain, and her condition proved later to be arthritic and not static. This seemed a little too good to be true, and I asked my colleague, Dr. Lloyd T. Brown, to repeat the clinical experiment the following year. He had the same good luck. The result had been economical for the hospital.

It seemed worth while to attempt to gain an impression of the incidence of faulty muscle balance in otherwise healthy young people. Through the

kindness of Miss Amy Homans, then professor of physical culture at Wellesley College, and Miss Randall, her assistant, the foot balance of 350 students was tested in the manner described. Faulty balances were found to be three times commoner than normal balances. Incidentally, Miss Randall reported that only a surprisingly small number of college girls were able to take walks of any considerable distance without general and foot fatigue. This was in 1912-1913, and it is to be hoped that the increase in athletics and the more sensible shoes have by now lessened the prevalence of foot strain in the female college students.

If, in the routine examination of a patient with a tired back and weary feet, one finds an abnormal wear of the shoes, indicating pronation, tenderness to pressure over the strained ligaments of the arches, the other classic signs of foot strain and a faulty muscle balance, what should be done? The first thing, in my opinion, is to make the patient understand what these findings mean in terms of his symptoms and the reasons why the measures proposed may be expected to relieve the symptoms that have induced him to seek advice. In my experience, this is time well spent.

As the first measure, one should recommend that shoes be designed on proper lines and of proper fit. One is inclined to inveigh against the modern ready-made shoe. It is true that the vagaries of fashion are responsible for many foot ills (especially the high heels with a small base), but one should pay a tribute to the manufacturers of shoes and the retailers of their products for their remarkable accomplishments. It is possible, except in the presence of fixed deformities, especially of the toes, to find for almost any shape of foot a ready made shoe that is both nondeforming and comfortable to wear. The detailed and extensive scientific work of Dr. R. Plato Schwartz,<sup>3</sup> professor of orthopedic surgery at the University of Rochester (New York), is worthy of unstinted praise in this connection, as are Professor Arthur Steindler's<sup>4</sup> excellent studies of the pathology of locomotion. The details of the mechanisms of the human gait are being accurately analyzed for the first time.

One should also correct or compensate for any departure from good weight-bearing lines that may be caused by improper body posture.

Moreover, one should make sure that there is no accessory inhibition, such as the lack of flexibility of the foot that is present when the power of dorsiflexion with the knee fully extended is less than a right angle because of contracted calf groups.

Finally, by some means, the normal muscle balance between the inverters or protectors of the

arches and the everters or depressors of the arches should be restored.

Other potential causes of foot strain should not be overlooked because of this emphasis on what I believe to be a neglected and remediable common cause. Fatigue, poor muscle tone after illness, unreasonably long hours of standing or walking on unreasonably hard surfaces, and vicious shoeing may be important etiologic factors. Overweight is often blamed, but in my experience the muscles usually develop in consonance with the gradual addition of weight if activity is maintained. The association of overweight, a sedentary life and foot strain was known in Biblical times, for in *II Samuel* (IX:13), we read, "So Mephibosheth dwelt in Jerusalem: for he did eat continually at the king's table; and was lame on both his feet."

How can a faulty muscle balance be changed into a normal one? "Aye there's the rub," for it entails exercises persistently followed and precisely performed. Most patients still expect a pill to cure their ills; almost as many pin their faith to an injection. A small number are willing to be massaged and exercised if the physical therapist does most of the work. Work on the patients' part is considered a personal virtue, although the reward of this virtue is their own betterment. If the explanation of the causes of their discomfort has been clear and convincing, I have found it possible to gain excellent co-operation from the vast majority of patients. The methods employed are those of dogmatism, cajolery and fear—not very idealistic methods, I admit, but productive of results.

I insist that patients take only one exercise, which is illustrated by the physician at the time of the visit. They are then presented with a carefully typewritten description of the exercise and four attractively colored marbles. The law of gradual increase in exercise is dogmatically laid down.

The patients are told that they must do these exercises between bed and breakfast, because muscles increase in strength only when they are rested before being exercised and have a chance to rest after being exercised. I remind them that the old adage still holds, "It is no use to whip tired horses," that although it is easier to do stupid exercises just before going to bed, it takes more "guts" when they are sleepy in the morning; if they go to bed without doing the exercises and get up that much earlier in the morning, their total sleeping time is no less and their muscular benefit much greater.

I inculcate fear by telling them that at the next visit—in two or three weeks—I shall be able to tell by the balance test whether or not they

have followed the instructions given. It has surprised me much to find how valuable an incentive to struggle such a fear of discovery of not having played the game often is.

The ready-made artificial foot supports commonly known as "foot plates" or "arch supporters," which stores and druggists carry, are, by and large, as much an abomination as one would expect a ready-made set of artificial teeth to be; but if intelligently fitted, such supports are often pain relievers, without having, as a rule, any curative value. I try to distribute the weight appropriately to the individual foot that needs a temporary support by making plaster casts, which are subsequently shaped to attain the desired end and from which light spring-steel or sponge-rubber supports are fashioned. I almost never make heavy or rigid foot supports, which tend to atrophy the intrinsic foot muscles. The type that is recommended for all but the rigid or very heavy or indolent patients provides a light springy support, which relieves the symptoms and holds the arches in position while the patients are attaining and learning how to maintain a normal muscle balance. Once this has been achieved and persevered in, artificial supports become unnecessary, and on any reasonably soft surface, weight bearing becomes a joy. One may even whisper the word "cure."

There have been very few disciples of this method of examination and therapy, although I have continued to employ it for over thirty years and still believe in its soundness. The fact that it is rarely used suggests very strongly that it is of little value, and yet I am somewhat comforted by the remembrance that Thomas's ring-hip splint remained almost unknown or at least unused except by him and a few colleagues for fifty years. But when his nephew, Sir Robert Jones, persuaded Sir Henry Gray, chief surgeon of the Third British Army, to order it applied to all the compound fractures of the thigh on the field before transportation to base hospitals, the mortality from this very common injury dropped from over 80 to 15 per cent. The Medical Department of the United States Army learned how to use this splint before casualties began, and it was the routine treatment prescribed throughout the course of the American Expeditionary Force. It proved an equal lifesaver for our soldiers. Today, all good ambulances are equipped with this almost forgotten splint or its modifications. "Splint 'em where they lie" is still a good slogan. It may be gathered that I think "Balance 'em where they stand" is another. Here is no thought of saving life but of enabling certain people to tread their measures with greater happiness and more comfort.

## DISCUSSION

DR FRANK R OBER (Boston) Dr Osgood has demonstrated a very simple and excellent method for testing the basic difficulty in foot strain—that is, muscular weakness. I agree with him that the term flat foot is a bad one. The average person who has a flat foot hardly ever has any trouble with his foot, because the shoe that is bought in the market fits a flat foot and no other foot, therefore, this person is always protected.

Painful symptoms may occur in any type of foot—a flat foot, a highly arched foot or a moderately arched foot. The highly arched foot is the one that gives the most difficulty, however.

The patient should be examined sitting as well as standing. No satisfactory examination of the feet can be made in the standing position alone. A patient may pronate in the standing position and be labeled with a diagnosis of flat foot, whereas, when the foot is examined in the sitting position, the arch may be much higher. This type of foot is not a flat foot. The feet flatten out on standing because the patient has short posterior calf muscles, and to get the heel down on the floor, the front of the foot must go somewhere and usually goes into the abducted position, causing the ankle to roll inward. If the patient is asked to stand on tiptoe, it will be noticed that his arch is restored to the normal position. However, if a patient has worn flat shoes for years, the medial ligaments become stretched out, so that it is impossible for the patient to support his foot in the normal position, even with the assistance of the muscles.

There have been various attempts to legislate the heights of heels. One may as well try to legislate window glass for spectacles, because no two feet are alike.

According to a certain insurance company, growing pains

in children are due to rheumatism. The fact of the matter is that 999 out of 1000 cases are due to foot strain. The patient with a strong foot can wear any type of shoe, but if this patient is sick in bed for two or three months or has some debilitating disease even his foot will go to pieces when weight is put on it. Patients with short heel cords are much better off with a shoe that has a heel high enough to compensate for the loss of dorsiflexion.

Exercises should be simplified as much as possible since most people object to doing many. One exercise that uses practically all the muscles of the foot is much more satisfactory. In this exercise the patient is asked to curl his toes downward and at the same time to invert and dorsiflex his foot. This exercise affects the plantar muscles of the foot, the toe flexors and the anterior and posterior tibial muscles, all of which are the main support of the arch.

The main trouble with the whole shoe situation is that shoes are manufactured on a mass production basis. Since no two feet are alike in a single person it is out of the question to expect such a shoe to fit all types of feet. However, if a shank could be made to go into the shoe that could be adjusted to fit the foot, this problem would be solved.

The foot muscle testing apparatus that Dr Osgood has discussed is a simple device, not only in checking the weakness in foot muscles but also in checking, from time to time how well and how faithfully the exercises are being carried out.

DR OSGOOD (closing) I agree with everything Dr Ober has said, but the object I have been trying to emphasize is to get rid of the necessity of artificial supports. I am convinced that it is possible to do so in a great many cases. One method of doing it is to test the protectors against the depressors and then, if the balance is wrong and the depressors are stronger, as they very often are, and if the patient co-operates the strength of the protectors can be built up to a normal muscular mechanism is attained.

It is rather good fun to be able to wear sneakers once in a while, and it is still a pleasure to play tennis. One cannot do that without normal muscle protection.

After what Dr Ober has said about ready made shoes I think I should say something in defense of the shoe manufacturer, because it is remarkable that so few of us have to have our shoes made for us. If we select carefully, most of us can find a shoe that fits reasonably well and, with a normal balance, can escape foot strain.

## TOXIC EFFECTS FROM THE INTRAPERITONEAL USE OF SULFANILAMIDE\*

### Report of Two Cases

MARK FALCON LESSES, M.D.,† AND ARNOLD STARR, M.D.‡

BOSTON

THE use of sulfanilamide as a local therapeutic agent for the prevention or treatment of peritonitis has recently been widely advocated.<sup>1-5</sup> Although the available reports attest its value, little mention is made of toxic effects such as those so frequently described following the oral administration of this drug.<sup>6</sup> Because of the desire to attain a high local concentration, the amounts used intraperitoneally (8 to 15 gm.) have been large when compared with the amounts given in single doses either by mouth or by vein. Extremely rapid absorption from the peritoneum occurs, with resultant high blood levels of sulfanilamide that are soon followed by a drop to low values, a decline probably due to quick disappearance of the drug from the peritoneal cavity. According to most observers, the blood sulfanilamide level is elevated for about forty-eight hours, the highest peak being reached within two to twelve hours.

Toxic effects from the rapid absorption of the massive doses usually employed might therefore be anticipated even more frequently than following its use by mouth. Yet Thompson, Brabson and Walker<sup>4</sup> observed in 59 cases of acute appendicitis treated with intra-abdominal sulfanilamide that no toxic reactions beyond cyanosis occurred, except for 1 case of jaundice, which they attributed to an associated streptococcal peritonitis. On the other hand, Jackson and Coller,<sup>7</sup> although they note the beneficial results of intraperitoneal sulfanilamide therapy in peritonitis, draw attention to the higher incidence of jaundice in these patients as contrasted with those who have received the drug only by mouth. Icterus developed in 6 out of 25 patients who received intraperitoneal sulfanilamide; they attributed the icterus to liver damage.

Two cases are herewith reported in which 8.0 and 12.0 gm. of sulfanilamide were employed intraperitoneally, with resultant toxic reactions in the form of anemia and leukopenia in one case, and anemia and hepatitis in the other.

### CASE REPORTS

**CASE 1.**§ A 62-year-old woman entered the Beth Israel Hospital on February 27, 1941, with the complaint of

abdominal pain. She had been well until 2 years previously, when she developed abdominal colic that gradually increased in severity. Three months before admission, she noted pain in the left upper quadrant following meals, as well as gaseous eructations and a feeling of distention. During this same period, the patient became constipated, and there were occasional episodes of rectal bleeding. She had lost 32 pounds in weight in the 4 months preceding admission. Concomitantly, there was pallor of the skin and exertional dyspnea. A roentgen-ray examination of the large bowel at another hospital was interpreted as showing carcinoma of the colon. The past, family and marital histories were noncontributory.

The positive findings on physical examination were moderate pallor of the skin, conjunctivas and mucous membranes, and a blood pressure of 150/85. The rest of the physical examination revealed no important deviations from the normal.

The urine was free of albumin, sugar, bile or abnormalities of the sediment. The blood showed a red-cell count of 3,250,000 with a hemoglobin of 40 per cent (Sahli), and a white-cell count of 6600, with 71 per cent neutrophils, 20 per cent lymphocytes, 8 per cent monocytes, and 1 per cent basophils. There was slight achromia of the red cells, with moderate variation in the size and shape of the cells, and occasional polychromatophilia; the platelets appeared normal in number. The blood nonprotein nitrogen was 27 mg. and the total protein was 4.9 gm. per 100 cc., with an albumin of 3.04 gm. and a globulin of 1.94 gm.

For 5 days, the patient was prepared for operation with enemas, saline laxatives, intravenous glucose and saline solutions, and a low-residue diet. A transfusion of 500 cc. of citrated whole blood was given the day before operation, without undue reaction. Following transfusion, the red-cell count was 4,590,000 with a hemoglobin of 64 per cent (Sahli), and the white-cell count was 13,800 with 92 per cent neutrophils, 6 per cent lymphocytes and 2 per cent monocytes; there was slight achromia, anisocytosis and poikilocytosis of the red cells.

On the 5th hospital day, laparotomy was performed under spinal anesthesia. A malignant lesion involving the hepatic flexure of the colon was found. There was free, cloudy fluid in the peritoneal cavity, with injected and granular loops of small bowel, indicating early peritonitis. A large carcinomatous mass invaded the right retroperitoneal region, and a perforation was present in the ascending colon just below the hepatic flexure, with slight leakage of intestinal contents. Because of the peritonitis, nothing more than a cecostomy was done; this procedure employed a Pezzar catheter, which was brought out through a short oblique incision in the right lower quadrant. Eight grams of sulfanilamide powder was distributed in the peritoneal cavity, especially about the cecostomy area. The incision was closed with mass sutures of silk, and the cecostomy wound was closed with interrupted catgut sutures.

Following operation, the temperature rose abruptly to about 103°F., and the pulse rate to 120. Pyrexia and

§We are indebted to Dr. Adolph Meltzer for permission to report this case.

tachycardia were maintained at or above these figures until death. Five hours after operation, the blood sulfanilamide level was 12.6 mg per 100 cc. A sharp drop in the red and white cells of the blood was present (Table 1), with a moderate drop in the hemoglobin but without relative neutropenia. On the day following operation, there was a further drop in the hemoglobin to 46 per cent (Sihli). The red-cell count remained about 2,500,000, and there was further leukopenia, the white cell count being 2700, with abundant granulocytes. The

which fecal material could be freely expressed into the peritoneal cavity. Within the ascending colon was a necrotic papillary tumor, 40 cm in width, completely encircling the bowel and extending above and below the papillary projections. The retroperitoneal tissues of the right lumbar gutter showed marked inflammatory changes, without free pus. No gross hemorrhage was evident. The tumor extended upward to the hepatic flexure, adhered to the head of the pancreas and was slightly fixed to the lower pole of the right kidney, ex-

TABLE 1 Laboratory Data in Case 1

patient's condition rapidly declined and death occurred 36 hours after operation. On the day of death the non protein nitrogen of the blood was 41 mg and the total protein was 3.9 gm per 100 cc. The blood sulfanilamide reading on the morning of death was 7.5 mg per 100 cc. Later that day, several hours before death—the patient was given 40 gm of sulfanilamide intravenously and a transfusion of 500 cc of citrated whole blood.

**Autopsy.** At post mortem examination, purulence was absent but the presence of pillow of the mucous membranes, which had been noted clinically, was confirmed.

There were inflammatory changes in the peritoneum extending into the right pelvis and to the viscera contiguous with the anterior abdominal wall. One hundred cubic centimeters of reddish brown purulent foul smelling material was noted in the abdomen situated between coils of bowel and in the pelvis. A carcinomatous mass adherent to all adjacent structures was present in the ascending colon just above the cecum.

There were congestion and edema of the lower lobes of both lungs.

The mucosa of the lower two thirds of the esophagus was red and injected, and showed numerous small dilated submucosal vessels, with small patches of gross hemorrhage in some areas, and diffuse submucosal hemorrhage in others. The mucosa and muscularis of the esophagus were, however, intact throughout. There was marked dilatation of the esophagus, which contained a considerable amount of brown, foul smelling fluid, similar to that observed in the stomach.

The stomach was of normal size and contained a considerable quantity of fluid similar to that noted in the esophagus. The entire mucosa was covered by a reddish mucoid exudate, and presented beneath its surface numerous areas of submucosal hemorrhage and many small dilated vessels. These gave an appearance of diffuse hemorrhage covering the lower two thirds of the mucosa of the stomach.

The duodenum presented the same appearance so far as hemorrhage was concerned, as the gastric esophageal mucosa, but these areas were less marked and lighter in color. There was involvement of the muscularis of the third portion of the duodenum by the primary tumor, but no break through the mucosa. There was no evidence of ulcer, tumor or hemorrhage in the small intestine.

Surrounding the cecostomy wound in the colon was a small amount of purulent, fecal smelling material. There was a 1.5-cm perforation in the ascending colon, from

tending to the root of the mesentery of the small intestine where several lymph nodes were involved. The liver weighed 1740 gm and was of normal size, shape and consistence. The right lobe was adherent to the tumor mass.

On microscopic examination, some of the bronchioles showed a moderate infiltration of leukocytes and lymphocytes in the fibrous tissue comprising the submucosal layer. The alveoli of the lower lobes appeared compressed and contained small scattered collections of polymorphonuclear leukocytes without fibrin between them. There was marked compression of the alveoli of the lower portion of the lower lobe.

The liver cells showed no degenerative changes. No metastases were present.

The submucosa of the stomach contained numerous blood vessels markedly distended with blood but without free hemorrhage. The same picture was seen in the duodenum.

The primary tumor in the colon was a relatively anaplastic adenocarcinoma. The regional lymph nodes were involved by metastases.

Bone marrow from a rib was moderately cellular and contained, predominantly, cells of the granulocytic series. A moderate number of megakaryocytes were seen but nucleated red blood cells were rare. The marrow contained a considerable amount of fat but no appreciable amount of fibrous tissue. No metastatic tumor formation was present.

Post mortem bacteriologic cultures from the heart's blood showed the presence of nonhemolytic streptococci and *Escherichia coli*, whereas cultures from the abdominal fluid contained the same organisms in addition to *Clostridium welchii*.

The patient died of a blood stream infection with nonhemolytic streptococci and *Esch. coli*, and generalized peritonitis caused by a perforation into the peritoneal cavity at the site of the adenocarcinoma of the ascending colon. The anemia evidenced by this patient before death was associated with hypoplasia of the red-cell elements of the bone marrow. The hemorrhagic lesions in the intestinal tract were terminal.

**Comment.** In this case, death was primarily due to septicemia and peritonitis from carcinomatous perforation of the colon but the development of marked anemia and leukopenia within 5 hours after laparotomy and intra peritoneal instillation of 80 gm of sulfanilamide must be ascribed to the toxic action of this drug. The bone

marrow was hypoplastic in red-cell elements. Although some of this hypoplasia undoubtedly antedated operation, the peripheral blood changes indicated that further depression occurred following the use of sulfanilamide. The marrow showed abundant cells of the granulocytic series, and this too was reflected in the blood stream in the maintenance of an adequate percentage of neutrophils. However, the white blood cells and the absolute number of neutrophils progressively declined, indicating failure of delivery of these cells to the blood stream from the marrow. Other possible mechanisms of blood destruction or blood loss were not operative since the septicemia was caused by nonhemolytic streptococci and *Esch. coli*, and

sediment. The blood nonprotein nitrogen was 26 mg. per 100 cc., and the icteric index 9.

Several hours after admission, laparotomy was performed under spinal anesthesia. The peritoneal cavity was filled with turbid brown fluid, which was aspirated and subsequently found to contain *Esch. coli*. An adherent cystic mass, 20 cm. in diameter, arising from the right ovary filled the pelvis. Its wall was congested and necrotic in patchy areas, and purulent fluid oozed from several perforations. The cyst was freed and removed. Its bed contained a mass of greenish-gray membranous tissue resembling the wall of an abscess. In view of the extensive nature of the infection, 12 gm. of

§After posterior colpotomy.  
¶After 500-cc. transfusion of whole blood.

the submucosal gastrointestinal hemorrhages were terminal and inadequate to account for the anemia.

Five hours after operation, the blood sulfanilamide level had risen to 12.6 mg. per 100 cc., indicating that rapid absorption had occurred. The patient also received 4.0 gm. of sulfanilamide intravenously, but this was given well after the onset of the anemia and shortly before death, so that it could not have contributed materially to the toxic reaction.

CASE 2. A 40-year-old woman entered the Beth Israel Hospital on February 15, 1941, complaining of right-sided lower abdominal pain of 6 hours' duration. One month prior to entry, there had been an attack of lower-right-quadrant pain, which subsided without treatment but was followed by symptoms of so-called "grippe," from which complete recovery had occurred. Twenty years previously, there had been an operation for disease of the right ovary.

Physical examination showed a dusky pallor of the skin. The temperature was 105°F., and the pulse rate 158. The abdomen was tense, spastic and diffusely tender. Vaginal examination revealed a moderate whitish discharge, no pain on motion of the cervix, and no abnormalities of the vaults. On bimanual examination, a firm, large, tender abdominal mass was felt in the midline, separate from the uterus. The blood pressure was 160/100. The heart was moderately enlarged to the left and regular in rhythm, with a faint, blowing apical systolic murmur. The lungs showed no abnormalities. The remainder of the physical examination was not noteworthy.

The blood showed a hemoglobin of 96 per cent (Sahli) and a white-cell count of 8600. The urine was acid, with a specific gravity of 1.015, and negative for albumin, sugar and bile, with a trace of acetone and with a normal

sulfanilamide was placed in the peritoneal cavity, and the wound was closed without drainage with interrupted silk-mass sutures. An intravenous infusion of 500 cc. of plasma was given during the operation.

After operation, the pulse and temperature persisted at high levels for about 5 days. In the 24 hours subsequent to laparotomy, the following therapy was administered: 2000 cc. of plasma, 500 cc. of citrated whole blood, 6.0 gm. of sulfanilamide intravenously and 5.0 gm. of sodium sulfathiazole intravenously. On the 2nd postoperative day, 2.0 gm. of sulfathiazole was administered by mouth. No additional chemotherapy was used.

Deep jaundice of the skin and mucous membranes developed 36 hours after operation. At the same time, signs of bilateral pneumonia became apparent both by physical and roentgen-ray examinations. Coincident with the appearance of the jaundice, there was a moderate drop in the red-cell count (Table 2) and the development of a marked bilirubinuria. The administration of sulfonamide compounds was immediately stopped, and although blood studies at intervals of 4 hours showed no further hemolysis, a transfusion of 500 cc. of citrated whole blood was given to return the blood to more normal levels. With the cessation of chemotherapy, no further anemia developed, and there was a gradual decline of the icteric index from its high value of 35 on the 2nd postoperative day to normal on the 14th, with disappearance of bilirubin from the urine. The pneumonia gradually subsided, and by the 6th postoperative day, the patient's condition was good, but the temperature had not quite returned to normal. From this time on, the convalescence was complicated by the development of a pelvic abscess, which manifested itself by leukocytosis and pyrexia and, later, by the appearance of a pelvic mass. This was drained through the posterior cul-de-sac on the

22nd postoperative day. A considerable quantity of foul, yellowish green pus was evacuated from the abscess cavity. Thence onward, recovery quickly ensued, and the patient left the hospital in good health on the 32nd day after entry.

**Comment.** This patient, critically ill with diffuse peritonitis, recovered following excision of a ruptured, gangrenous ovarian cyst, and the intraperitoneal instillation of 120 gm of sulfanilamide. However, jaundice and anemia developed as a toxic reaction. The intensity and duration of the bilirubinuria indicated that the jaundice was primarily due to toxic hepatitis, for the moderate hemolysis of the blood could have contributed only a small amount of the increased bilirubin. The blood sulfanilamide level rose to 4.5 mg per 100 cc on the morning following operation, and to 7.0 mg per 100 cc on the next day, with complete disappearance from the blood stream by the 6th postoperative day.\*

### Discussion

During the past year, the value of the intraperitoneal use of sulfanilamide in peritonitis has been stressed by several authors, with emphasis on the lack of toxic reactions. Jackson and Collier,<sup>7</sup> however, have already remarked on the increased incidence of jaundice, and the 2 cases herein reported are further evidence of the toxicity of sulfanilamide when given intraperitoneally in large doses. There has been a gradual replacement of sulfanilamide by sulfapyridine, sulfathiazole and other sulfonamide compounds for oral and parenteral therapy, not only because of their greater efficacy but also because of apparent decreased toxicity. The same consideration may well apply to the intraperitoneal application of sulfanilamide, a drug initially selected because of its greater solubility. But this very property causes such rapid absorption that Jackson and Collier believe it doubtful whether the primary local effect lasts more than one or two hours. Throckmorton<sup>8</sup> also found that after six to twelve hours there was no gross evidence of sulfanilamide placed in the peritoneum of rats, in contrast to sulfathiazole, which remained grossly visible for three to six days. This greater solubility not only militates against prolonged local action, but also exposes the entire organism to undesirable reactions. Even the inflamed peritoneum rapidly absorbs sulfanilamide, as is well shown by the speedy elevation of the blood level. Although blood levels are not an index of continued intraperitoneal activity, the peritoneum is such an effective absorbing surface that the duration of local action of a soluble substance like sulfanilamide is necessarily short.

The systemic effect of intraperitoneal sulfanilamide approaches that seen following intravenous administration because of the speed with which high blood levels are reached, and there is prob-

bly a more toxic action on the liver than with oral administration because of the site of application. Jackson<sup>9</sup> found a 30 to 40 per cent higher level of sulfanilamide in the portal blood of dogs that had received intraperitoneal sulfanilamide as compared with the level in jugular blood, and suggested that the jaundice might be due to liver damage caused by these high portal levels. In this connection, Bieter and his co-workers<sup>10</sup> have shown in chickens that, even with orally administered sulfonamides, there is selective concentration of sulfanilamide in the liver, as contrasted with sulfapyridine or sulfathiazole.

Goodwin and Findlay,<sup>11</sup> in an experimental investigation of locally applied sulfonamide drugs, pointed out that it is possible to obtain an effective concentration in the blood with locally applied sulfanilamide but not with sulfapyridine or sulfathiazole. The latter substances are removed too slowly from the site of application for any measurable blood concentration to be produced. Throckmorton's<sup>8</sup> experiments on rats, however, indicate that sulfapyridine may be injurious to the peritoneum in contrast to sulfathiazole, which does not cause peritoneal damage and which furthermore has such delayed absorption that the local defense mechanism is augmented by the foreign-body reaction. On the basis of the solubilities and available evidence, therefore, one would be justified in using sulfathiazole rather than sulfanilamide if prolonged intraperitoneal action is desired with minimal general effects.

### SUMMARY

Two cases are reported in which the intraperitoneal use of sulfanilamide in massive single doses caused anemia, leukopenia and hepatitis.

The substitution of a less soluble sulfonamide such as sulfathiazole for intraperitoneal use is suggested.

\*The concentration of sulfanilamide in this patient rose to a level intravenously during the twenty-four hours subsequent to operation may well have contributed to the toxic hepatitis, but was probably not the precipitating factor. There is some doubt as to the interval between the intravenous administration of the drug and the onset of the jaundice, and by the 1% incidence of hepatitis (0.6 per cent in a series of 1000 cases as reported by Long and Starr) following the oral modes of administration, sulfanilamide

## CLINICAL NOTE

TREATMENT OF  
TRICHOMONAL VAGINITIS  
WITH ACETARSONE TAMPONS

JOE V. MEIGS, M.D.\*

BOSTON

IN 1933, Gellhorn<sup>1</sup> advocated the use of acetarsone (Stovarsol) in a powder blower for the treatment of vaginitis due to *Trichomonas vaginalis*. His results were superior to any he had obtained by other methods. Acetarsone is an arsenical and as such may be considered moderately dangerous, but no untoward results were present in Gellhorn's series.

This treatment is usually given in the physician's office and necessitates frequent visits. Hence, it seemed advisable to devise a means for carrying out the treatment at home. This appeared possible by the use of tampons (Tampax) infiltrated with acetarsone, and arrangements were made with a pharmaceutical house for their preparation. It was hoped that these medical tampons would absorb the discharge and control the infection. Since 1938, a number of patients have been treated by this method.

The tampons† are made up by dusting each with  $1\frac{1}{2}$  gr. of acetarsone; in addition, a tablet containing  $\frac{1}{2}$  gr. of acetarsone, 2 gr. each of glucose, lactose and boric acid,  $\frac{1}{2}$  gr. of starch,  $\frac{1}{4}$  gr. of sodium bicarbonate and  $4/10$  gr. of tartaric acid is placed on the top of each tampon. The pH of the solution of this tablet is approximately 3.0.

In each case, after the diagnosis had been made by examination of a drop of discharge, diluted with two or three drops of warm water, under the high-dry lens of the microscope, the patient was treated with an acetarsone-powder insufflation and then was given the medicated tampons to use at home. For the first week, the tampons were used every night or were inserted in the morning and removed at night. The latter method prevented the discharge from irritating the vulva while the patient was on her feet. At the end of a week, a warm douche of sodium perborate (one tablespoonful to a quart of warm water) was taken, to remove the accumulated powder. During the next week, the tampons were inserted every other day, and during the following week, they were used every third day, the weekly douches

being repeated. This went on until the next menstrual period. The medicated tampons were used throughout the period, but after it had ceased, the treatment was omitted for a few days and a smear taken during an office visit. If this was positive, the same treatment was repeated. If the smear was negative, the patient was told to use a tampon twice a week, with a sodium perborate douche at the end of the week. If, after the next period, the vagina was still free from the organism, treatment was stopped.

As part of the treatment, patients were advised to wipe the anus after a bowel movement from front to back and not from back to front, for it is possible that *Trich. hominis* may infect the vagina. Furthermore, all patients were advised to wash their hands carefully both before and after going to the toilet. Absolute cleanliness is necessary, since reinfection of the vagina and vulva may result from chance contamination.

Thirty-nine patients were treated. The duration of the infection was a matter of days in some and of months or years in others. Of the 39 patients, 33 were given one series of treatments; 5, two series; and 1, four series. In 19 cases, the treatment was successful, that is, a negative smear that remained negative after two successive menstrual periods was obtained. In 10 cases, negative smears were not obtained but the patients obtained considerable relief of symptoms; in 6, there was a complete failure. In 4 cases, the treatment was successful the first time but the disease recurred. In 4 patients who had been treated by other methods, the tampon treatment was successful.

Of the 39 patients treated, 26 considered the treatment satisfactory, 6 thought that it was not, and 7 were not sure whether it was helpful or not. In no case was any reaction to arsenic noted. In only a few cases was the treatment given up because of the patient's inability to use the tampons; however, the method was seldom used in young girls.

## SUMMARY

The use of medicated tampons containing acetarsone (Stovarsol) is a satisfactory method for the home treatment of patients with vaginitis due to *Trichomonas vaginalis*.

Of 39 patients treated in this way during the past three years, 19 were permanently cured and 7 more were symptomatically relieved.

## MEDICAL PROGRESS

## NUTRITIONAL DEFICIENCIES IN RELATION TO THE DIGESTIVE TRACT

CHESTER M. JONES, M.D.\*

BOSTON

WITH the realization that specific food substances may affect in a striking manner the production of such diseases as scurvy, rickets, pernicious anemia and similar conditions, much of the investigative work of recent years has concerned itself with an attempt to clarify the action of specific nutritive components on tissue and organic function. The availability of various specific vitamins has further led to numerous observations on the effects of these substances on individual diseases, such as pellagra, and on the manifestations of more general pathologic conditions. Because, in specific deficiency states, almost miraculous clinical changes may be obtained by the use of replacement therapy, there has been a natural, although poorly directed, application of these results to a large number of conditions without critical or well-controlled studies. Such therapeutic enthusiasm, although understandable, is to be regretted because much of it involves wishful thinking and leads to needless and frequently useless forms of therapy at moderate or great expense to the patient. It is pertinent, therefore, to present a few of the numerous studies on the relation between specific nutritional factors and digestive-tract function that have been made by various observers.

As Youmans<sup>1</sup> has been careful to point out, there is very little scientific evidence of the exact effect that vitamin deficiencies exert on disease, and hence little justification for much of the widespread use of vitamins as therapeutic agents in a great number of illnesses. As he states, there is good reason to believe that vitamin deficiencies do occur as complications of many diseases and modify unfavorably their course and outcome. For the present, however, the influence of vitamin deficiencies must be considered to be that which might reasonably be expected from poor general nutrition. There is little reason to doubt that mild or subclinical pellagra has an effect on the course of other illnesses, but no specific information is as yet available of the exact effect that such a deficiency produces. The fact that no good clin-

ical test for most hypovitaminoses exists gives most deductions a speculative rather than a truly scientific value.

Further limitations to the value of clinical or animal investigations are obvious when one remembers, as Spies and his group<sup>2</sup> point out, that vitamin B, which was formerly considered a single substance, is probably composed of twelve or more separate factors, each of which together with unknown substances contributes to the total effect of various therapeutic agents, such as yeast, wheat germ and liver extract. The wisdom of general replacement therapy is borne out by his experiences at the Hillman Hospital, where studies were made on a group of 1250 consecutive cases of malnutrition. In addition to specific vitamin lacks, it was noted, for example, that a large number of persons received as little as 50 per cent of the estimated energy requirements, and in many cases the protein intake was too low to maintain nitrogen equilibrium. Nearly all the patients received substandard amounts of calcium, phosphorus and iron, and none obtained standard amounts of all three elements. Spies and his collaborators stressed the value of administering water-soluble and fat-soluble vitamins together, rather than as individual prescriptions, as the most useful method of treating most deficiencies. Mackie et al.,<sup>3</sup> in an excellent review of vitamin deficiency in gastrointestinal disease, stress the point that symptoms may be produced because of certain disturbances of normal body chemistry due to avitaminosis without demonstrable clinical evidence of disease except in a few cases. They also point out the frequently forgotten fact that many of the dietary regimes in vogue for the treatment of diseases of the digestive system are open to grave suspicion so far as adequacy of food constituents is concerned. A practical consideration of some of the causes leading to avitaminosis is indicated in a paper by Rosenblum and Jolliffe,<sup>4</sup> who observe that various therapeutic maneuvers very definitely contribute to vitamin lack or interfere with the normal utilization of the vitamins that are being administered. In the presence of alkali therapy, orally administered ascorbic acid, thiamin chloride, riboflavin and perhaps other vitamins are inactivated or destroyed. Absorption of large amounts of these and other vitamins may be associated with the use of col-

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C. Thomas Company, Inc., \$4.00).

\*Clinical professor of medicine, Harvard Medical School; physician, Massachusetts General Hospital.

loidal aluminum hydroxide or of magnesium trisilicate. Oral treatment with the fat-soluble vitamins may definitely be adversely affected by the associated ingestion of liquid petrolatum. From the surgical aspect, a too liberal use of fluids parenterally, in the form of glucose solutions, contributes distinctly to the increased elimination of members of the vitamin B complex, and is particularly undesirable when operative procedures on the gastrointestinal tract have been performed. A similar danger prevails in other states in which parenteral feeding is necessary.

Numerous references to the effect of already existing gastrointestinal disease on the production of dietary deficiencies are to be found. Brown,<sup>5</sup> along with many others, mentions the occurrence of various deficiency states secondary to prolonged vomiting, diarrhea and the like. In addition, he is authority for the statement, which is probably correct, that actual ulcerative disease of the colon may occur as the aftermath of a poorly balanced diet, particularly when associated with unusual stress, such as intercurrent infection or pregnancy. He mentions the finding of frank ulcerations of the colon resulting from such conditions. Exact proof for such statements is still lacking, but there can be no doubt that at times profound organic changes occur at different levels of the digestive tract as the result of general or specific malnutrition. Bean and Spies<sup>6</sup> mention their findings in 100 persons studied in an area of endemic pellagra, beriberi and riboflavin deficiency, who developed such symptoms as a complication of chronic diarrhea. They also note that chronic diarrhea itself predisposes to the development of deficiency syndromes because of increased loss of nutritive products and decreased absorption, and they also point out that if the diarrhea is relieved, even without vitamin therapy the secondary deficiency is usually improved. In their article, these authors advocate, as many others do, the use of parenteral injections of crystalline vitamins in the presence of active diarrhea because these substances are lost when given orally. They insist, however, that in most cases parenterally given vitamin preparations do not take the place of a high-protein, high-calorie diet, together with large doses of nicotinic acid, thiamin hydrochloride and riboflavin. They suggest the daily use of between 500 and 1000 mg. of nicotinic acid amid, 10 to 50 mg. of thiamin hydrochloride, and 2 to 10 mg. of riboflavin during the acute manifestations of deficiency.

Among the objective changes in the alimentary tract that are properly attributed to avitaminosis, Wilbur<sup>7</sup> mentions the symptoms of anorexia and diarrhea, abnormalities in function, such as achlorhydria, alterations of the motor and absorptive activities of the intestine, and such lesions as stoma-

titis, glossitis, proctitis, and atrophy and inflammation of the gastric and intestinal mucosa. Although proof of the exact etiology of any or all of these changes is still incomplete, he quite rightly stresses the benefit of careful inspection of the oral cavity, analysis of gastric contents, x-ray films of the alimentary tract with particular reference to the small intestine, and other searches for vitamin deficiency, such as the demonstration of peripheral neuritis, edema and night blindness. These conceptions are not new but are worthy of repetition.

That the function of the bowel is seriously interfered with in the presence of deficiency disease has been noted by various observers. For example, Groen<sup>8</sup> has shown that the absorption of glucose from the small intestine is distinctly interfered with in various deficiency conditions and can be restored to normal by proper replacement therapy. Similarly, Beams, Free and Glenn,<sup>9</sup> in studying patients with pellagra and nontropical sprue, found impaired absorption of galactose, with improvement, at least in patients suffering from pellagra, following specific therapy. They also noted that several cases of rosacea keratitis, which responded to riboflavin therapy, gave indication of increased galactose absorption that later improved, with the disappearance of the skin lesions.

Changes in the gastric mucosa in numerous deficiency diseases have been mentioned by various investigators and need only be noted briefly to indicate the effect of such a change in rounding out the vicious circle of malnutrition. X-ray evidences of disturbed motor or absorptive function in the small bowel have been noted by numerous investigators in patients suffering from various forms of dietary lack. These changes, for the most part, are in association with diarrheal states and are demonstrable as changes in tone, caliber and motility of the small bowel or as complete disappearance of the distinctive mucosal markings. Evidence has been produced that they may be effected by protein deficiency or by lack of various members of the B complex. A too exact interpretation of the x-ray findings mentioned by Kantor,<sup>10</sup> Mackie,<sup>11</sup> Golden,<sup>12</sup> Tyler<sup>13</sup> and others should not be attempted at the present time. Perusal of various articles that have appeared in recent years on this particular phase of small-bowel disturbance leads to the conclusion that strict deductions about functional or cellular changes in the small bowel, as evidenced by x-ray studies, should be made with extreme caution. That such changes may be seen in idiopathic steatorrhea, advanced ulcerative colitis, tropical sprue, infantile celiac disease, pellagra and other conditions is undoubtedly true. As Mackie properly points out, however, such a "deficiency pattern" may occur in a variety of conditions, such as nephrosis, diabetes

insipidus, diseases of the mesenteric lymphatics, abdominal cancer and certain jaundiced states. He also mentions a most interesting fact, which as yet is unexplained—namely, that the same alterations in mucosal pattern can be observed in the intestine of the normal newborn infant. Since these changes disappear early in life and since degeneration of the nerve cells of the myenteric plexuses in adults presenting the deficiency pattern has been demonstrated, these modifications of the normal mucosal pattern of the small bowel are probably the result of interference with the intrinsic nervous mechanism. Confirmation of such a hypothesis, in my experience, may be found in the histologic demonstration of profound atrophic changes existing in Auerbach's and Meissner's plexuses in patients dying with advanced pellagra. According to Mackie and others, such changes can usually be reversed by the enthusiastic administration of the B complex in the form of crude liver extract and yeast. The more concentrated preparations, as a rule, are less effective or may be ineffective. A detailed description of the radiologic changes in the small bowel supposedly secondary to vitamin B deficiency is given by Golden,<sup>12</sup> but it should be stated that as yet not all radiologists are in entire agreement with this author.

An interesting and moot question is that of the interrelation of deficiency disease and resistance to infection. Riddle, Spies and Hudson<sup>14</sup> have made certain interesting observations on 150 selected cases of pellagra, riboflavin deficiency and beriberi. Before, during and after treatment, the bacterial flora of the lesions associated with various vitamin deficiencies was investigated, and certain immune reactions were studied. The lesions at the corner of the mouth characteristic of riboflavin deficiency were found to contain pure or nearly pure cultures of certain strains of *Staphylococcus aureus* in 80 per cent of the cases, and in the remaining 20 per cent *Streptococcus hemolyticus* predominated. Following the oral or intravenous administration of riboflavin or of substances rich in it, the fissures healed rapidly, and the organisms were no longer demonstrable. A study of the bacterial flora of the conjunctival sacs was made in cases of deficiency disease with associated conjunctivitis, and hemolytic strains of *Staph. aureus* were found to predominate in half of 30 cases. In addition to large numbers of Vincent's organisms, two thirds of the patients showing ulcerations of the tongue, gums or buccal mucosa yielded hemolytic streptococci, and the remaining third showed hemolytic strains of *Staph. aureus*. Following specific therapy with anti-pellagic substances, the bacterial flora, including the Vincent's organisms, promptly disappeared.

Apparently, a low complement titer existed in many of the acutely deficient patients and rose coincidentally with clinical improvement. In the whole blood of acutely deficient patients, there was a distinct depression in the bactericidal power for *Staph. aureus*, but little, if any, diminution was noted in the subclinical or mild cases of deficiency. Chapman and Harris<sup>15</sup> observed that monkeys maintained on certain vitamin-deficient diets developed a tendency to oral lesions accompanied by an increase in the fusospirochetal flora. This was apparently in association with diets deficient in parts of the vitamin B<sub>2</sub> complex. Those animals on an adequate stock diet tended to resist the artificial implants of the fusospirochetal flora under the severest of test conditions. The presence of glossitis, buccal aphthae and similar changes is a well-known accompaniment of various deficiency states, and the response to certain members of the vitamin B complex is now generally recognized. It is still essential, however, to stress the fact that careful observation of the tongue frequently yields a clue to an otherwise subclinical deficiency condition existing in patients requiring surgery of the gastrointestinal tract and may indicate the need for more than average care in the preoperative preparation. The report of Manson-Bahr<sup>16</sup> includes a very complete discussion of glossitis, with particular reference to vitamin B<sub>2</sub> deficiency in pellagra, sprue and allied states. Among other interesting facts, the author mentions a study of 500 cases of tropical sprue seen in India, Burma and other oriental countries. In three fourths of these patients, striking glossitis was one of the most prominent symptoms even when no anemia was observed. Improvement following the use of nicotinic acid was rapid, and corresponded to the results obtained in pellagra and certain other conditions. Manson-Bahr also points out the important consideration that changes in the buccal mucosa and tongue may be the result of nicotinic acid or riboflavin deficiency incident to an underlying pathologic condition.

Numerous studies on individual vitamin requirements and deficiency are of interest. It is generally admitted that the absolute requirements of the various specific food substances are still not known. The work of Elsom and Machella<sup>17</sup> on the intake of thiamin and its relation to other dietary constituents in food selected by normal subjects is of interest. Observations on a small group of normal subjects showed that the average daily intake of thiamin exceeded the theoretical requirement by 40 per cent, but the individual intake ranged from 6 to 115 per cent above the so-called "maintenance need." There was a tremendous variation of thiamin intake on individual days in the

The relation between vitamin C deficiency and peptic ulcer still continues to be studied. That low plasma levels of ascorbic acid are commonly encountered in patients suffering from peptic ulcer is well known, and there is every reason to believe that this lack is occasioned by dietary restrictions rather than that the vitamin deficiency itself has anything to do with the etiology of gastric or duodenal ulceration. Once established, however, such a deficiency may retard healing, and for this reason, as in other chronic diseases, it is essential to maintain a balanced diet, and the administration of optimum doses of vitamin C may assume real clinical value as a detail in ulcer therapy. The frequency with which vitamin C lack exists in gastric disease is illustrated by the dietary histories obtained by Ludden and his group<sup>34</sup> in a number of patients selected from the gastrointestinal and surgical clinics of the Bellevue Hospital. Dietary histories of this group of patients revealed that voluntary or prescribed diets had been very low in vitamin C. Twenty-three of 28 patients had gastric lesions; of the entire group, 1 had frank clinical scurvy, and 26 had subclinical scurvy, as indicated by laboratory data. In these patients, doses ranging from 1.5 to 11.4 gm., given from three to seventeen days, were necessary to bring about "saturation." A maintenance dosage of as high as 200 mg. daily was needed in a patient with a total gastrectomy, but other patients studied with gastric lesions conformed to the usual accepted maintenance requirements. Field et al.<sup>35</sup> report on their findings in 58 patients with peptic ulcer. They demonstrated in 29 patients that the plasma ascorbic acid values were below 0.5 mg. per 100 cc.; 10 out of 12 who were admitted to the hospital with hemorrhage had values below 0.4 mg. per 100 cc. The authors are probably correct in ascribing significance to the fact that in 2 patients in this latter group, bleeding occurred after they had been maintained on an ulcer regime for eighteen and twenty-six days respectively. Field calls attention to the need for vitamin C therapy as a valuable adjunct in the treatment of peptic ulcer and again stresses the fact that alkali therapy in ulcer patients may contribute to the deficiency in this vitamin and in vitamin B<sub>1</sub>. Ingalls and Warren<sup>36</sup> present even more striking figures so far as the actual plasma levels of vitamin C in patients with ulcer are concerned. Eighteen out of 20 patients had low plasma values for this vitamin. Six, whose histories included previous hemorrhages, had blood levels of 0.2 mg. per 100 cc. or less. Further evidence that deficiency diseases are usually multiple is found in the report from the Hillman Hospital<sup>37</sup> on blood and plasma ascorbic acid concentrations in patients with pellagra and associated deficiency diseases. Marked reduction

in blood values was found in many of the group studied, and the comment is made that these studies were carried out at a period when leafy vegetables and berries had been available to the patients for some time. In all probability, much greater deficiencies of vitamin C could have been demonstrated in the winter months.

The relation between the fat-soluble vitamins and disturbances of the gastrointestinal tract has been the basis of some studies. The absorption of carotene, the precursor of vitamin A, was studied by means of isolated intestinal loops by Irvin, Kopala and Johnston.<sup>38</sup> In the absence of bile or pancreatic lipase, only insignificant amounts are absorbed in the small bowel, but the addition of either or both of these substances affects absorption materially, and the addition of pure bile salts still further increases the amount of carotene absorbed. Previous reports on the inhibitory effect of mineral oil on the absorption of carotene are confirmed. May and McCreary<sup>39</sup> measured the amount of absorption of vitamin A in infants and children during various stages of celiac disease, or in children with the celiac syndrome secondary to other disorders. A low rise in the level of vitamin A in the vitamin-absorption test was a constant feature of celiac disease, and a similar finding was frequently observed in other conditions simulating this disease. Although not diagnostic of celiac disease, the test for vitamin A absorption described by these authors is helpful in following the clinical progress of recovery from celiac disease, since vitamin A absorption appears to return to normal when cure is complete. The level of blood carotene in celiac disease also seems to follow the clinical course of the disease, being low during the active stage and rising during improvement. Interference with the rise in plasma vitamin A following the ingestion of this substance was also noted by Ralli and his collaborators<sup>40</sup> in patients with liver disease and is in keeping with the finding of a low concentration of the vitamin, as previously noted in cirrhotic livers.

Studies on the effect of vitamin A deficiency on gastric function by Dyer and Roe<sup>41</sup> and by Herrin<sup>42</sup> indicate that lack of this vitamin does not, in animals, diminish the secretory power of the gastric cells or, to any important degree, the motility of the stomach. Some enthusiastic comments on the clinical use of vitamin A, with resulting improvement of gastric secretion in cases of achlorhydria, and more particularly in the successful treatment of peptic ulcer, are to be found in the reports of Földes and Vajda<sup>43</sup> and of Seelig.<sup>44</sup> The studies, although interesting, are far from convincing.

The keratinization of squamous-cell mucous membranes and the proliferation of epithelial cells

have been noted by various investigators of deficiency of this fat-soluble vitamin. The finding of proliferative changes in the columnar cells of the mucosal lining of the stomach in rats by Fridericia et al.<sup>45</sup> in the presence of vitamin A deficiency is therefore of some interest. Of particular significance are the observations that, in their experiments, gastric mucosal lesions occurred in animals kept on alternating deficient and normal diets for many weeks, but that restoration to a normal diet for a year reversed the changes that apparently had taken place in most of the animals. A somewhat similar study by Beck and Peacock<sup>46</sup> demonstrated that animals kept on a vitamin A deficient diet for a year developed ulcerations and papillomatous lesions of the forestomach. No alteration in intestinal permeability to bacterial toxins could be demonstrated, however, by Stryker and Janota<sup>47</sup> in animals on prolonged vitamin A deficiencies.

Abels et al.<sup>48</sup> found low plasma levels for vitamin A in the majority of patients with gastrointestinal cancer, but believed that this could be explained on the basis of an inadequate ingestion and absorption of the vitamin or an associated hepatic dysfunction so far as the storage of vitamin A or its formation from carotene was concerned. The fact that the plasma levels of vitamin A could be increased in these patients by the administration of yeast and lipocain, which are free of carotenoids, can probably be explained on the basis of the lipotropic action of these substances. It is also possible, however, that these patients presented other deficiencies due to inadequate food intake, and that the administration of yeast resulted, among other things, in better intestinal absorption.

The whole problem of hypovitaminosis of all fat-soluble vitamins caused by steatorrhea is presented in unusually complete form in the report of Albright and Stewart.<sup>49</sup> These authors emphasize the fact that pan-fat-soluble vitamin deficiency should be looked for in all cases of chronic diarrhea, regardless of the presenting symptom, and that when possible these patients should be given fat-soluble vitamins in fat-free vehicles, to obtain maximum dosage and maximum absorption. Such a consideration is of particular value in diseases like ileitis and ulcerative colitis, in which, as Mackie, Albright and others have demonstrated, a prothrombin lack with subsequent spontaneous bleeding may be a major clinical feature. That general nutritional deficiency states may include evidence of vitamin K lack, as well as that of other fat-soluble vitamins, is indicated by the study of Warner, Spies and Owen.<sup>50</sup> Forty-eight patients seen in the nutritional clinic of the Hill-

man Hospital with evidence of deficiency of one or more of the factors of the vitamin B complex were observed with relation to the prothrombin level and compared with a series of 37 patients on the Medical Service of the Iowa University Medical School. In both groups, moderate hypoprothrombinemia was demonstrated, a higher percentage being found in the patients seen in the northern clinic. The findings did not seem to be the result of vitamin K deficiency, however, in most cases, since large doses of this vitamin did not influence the prothrombin level. It was believed that the subnormal prothrombin production was rather the result of general debility than of nutritional deficiency alone.

\* \* \*

It is obvious that significant additions are being made gradually to information regarding the relation between nutritional disturbance and the function of the digestive tract. In the absence of easily applied clinical tests for avitaminoses and in the presence of many empty spaces in knowledge of the pathologic physiology associated with deficiency disease, it is the part of wisdom to treat any condition of deficiency as one with multiple components by means of those easily available food substances that can be readily obtained and taken orally. In certain cases, parenteral therapy is, of course, indicated, but every attempt should be made to utilize the oral administration of substances such as yeast, adequate amounts of protein and a really well-balanced diet.

The first category, the unusual bone conditions, can probably be excluded, although at one time I made a list of forty-five different conditions that I have seen erroneously diagnosed as osteogenic sarcoma. The inflammatory conditions—tuberculosis, syphilis and osteomyelitis—must be considered. The joint was not involved. There was no evidence of tuberculosis elsewhere. The blood Hinton reaction was negative. Osteomyelitis is not suggested by either the physical examination or the laboratory findings. Metabolic disease may be well ruled out, for the blood chemical findings were normal, and there was no evidence of any disease of the other bones. The general physical examination was not remarkable, except that the patient was a rather slender man.

So far as metastatic tumors are concerned, there is no evidence of any tumor as a primary source of metastases. This condition had existed for three and a half years since the onset. The duration was one and a half years at the first admission, and the second admission was two and a half years later.

That brings us down to a primary tumor, either benign or malignant. A history of trauma is obtained in about 40 per cent of the cases of primary bone tumors. I think it is fairly safe to say that the tumor in this case was not malignant, for a malignant bone tumor would give some evidence of remote metastases three and a half years after onset. Giant-cell tumors often appear after injury in the humerus and in the knee. In the femur, they are apt to arise in the inner condyle; in the humerus, in the outer condyle. They originate in the medulla, cause bone destruction, extend to the cartilage, as this one did, without breaking through into the joint, and form an expanding bone tumor.

This x-ray film, I take it, is an early one. The outline of the periosteum is unbroken except at one point. There is some expansion in this other film. The gross description of the tumor removed at the first operation is certainly compatible with that of a giant-cell tumor.

These tumors appear in two forms: a currant-jelly-like, very vascular tissue, and fibrous tissue that is yellow in color, probably owing to deposits of hemosiderin and lipoid material. Following the first operation, the patient received x-ray treatment with no appreciable improvement, and he re-entered with essentially the same condition—a little more advanced. The second x-ray film shows bulging of the internal condyle down to the joint surface. I think that the limitation of motion was partly due to mechanical interference.

My diagnosis in this case is giant-cell tumor. Such tumors are cured at times by excision or

curettage, at times by radiation; in a study of a large series, about 30 per cent of the patients were not cured by either method and came eventually to amputation. About 7 per cent undergo malignant change. As I have seen these cases, the defect never fills up with normal bone, and if bone chips are placed in the cavity after curetting they are absorbed. My diagnosis is giant-cell tumor, running the course that many of them do.

DR. TRACY B. MALLORY: You would not be seriously worried over the possibility of malignant tumor?

DR. SIMMONS: No; I should not.

#### CLINICAL DIAGNOSIS

Giant-cell tumor, right elbow.

#### DR. SIMMONS'S DIAGNOSIS

Giant-cell tumor of humerus.

#### ANATOMICAL DIAGNOSIS

Giant-cell tumor of humerus.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: This lesion was once again curetted, and the gross material on this occasion was rather fibrous, with many yellow spots in it. It did not show any of the currant-jelly appearance. On microscopic examination, there are areas of quite characteristic giant-cell tumor. These are interspersed with areas of rather dense fibrosis in which a good many cholesterol-filled foam cells are found. There are a few trabeculae and osteoid material, but nothing that suggests malignant lesions. I suspect that the unusual degree of fibrosis could perhaps be attributed to the x-ray treatment that the patient had received off and on during this period.

DR. SIMMONS: I think that is the usual story—increased fibrosis following either curettage or x-ray treatment. The cavity never fills in with normal bone.

DR. GEORGE W. HOLMES: I should like to know, although I was present at the time this question of operation was discussed, just why they operated. I presume that it was to improve function, and I wonder if operation would improve function, because there is nothing in the lesion as I see it in the x-ray film to make me think of a malignant tumor; as a matter of fact, it really did improve somewhat under radiation. The outlines are sharp, it has not grown any in two years, and although it has not filled in with new bone, it is at least quiescent.

DR. MALLORY: The patient, who was a manual worker, had considerable limitation of function and found it difficult to work.

## CASE 28141

## PRESENTATION OF CASE

*First admission.* A thirty-five-year-old Russian butcher's helper was admitted to the hospital because of pain and disability in the right elbow for one month.

A year before entry, the right elbow was slammed by the door of an auto in which the patient was riding. There was considerable local pain at the time, but no swelling, discoloration or actual disability was noted. Since then, he had experienced occasional slight pain along the inner aspect of the elbow. In the month before entry, the pain tended to become severer, and he was unable to straighten the elbow fully. There were no constitutional symptoms.

On admission, the patient appeared thin and pallid. There was a smooth, rounded swelling over the internal condyle of the right humerus, enlarging this landmark to about twice its normal size. The skin overlying this mass was not attached, or otherwise altered. The mass was tender posteriorly only (in the region of the ulnar nerve). Extension was limited by about 20°, but other movements were normal. There was no evidence of interference with the ulnar nerve. The other extremities were normal, and the rest of the physical examination was negative.

The temperature, pulse, respirations and blood pressure were normal.

Examination of the blood showed a red-cell count of 4,800,000, and a white-cell count of 10,500 with 72 per cent polymorphonuclears. The blood calcium was 11.0 mg. and the phosphorus was 3.3 mg. per 100 cc.; the phosphatase was 3.4 Bodansky units. The blood Hinton reaction was negative. The total cholesterol was 114 mg. per 100 cc.

A roentgenogram showed a multilocular cystic area in the medial condyle of the right humerus. The bone appeared thickened anteriorly, without interruption of the cortex. The upper aspect of the facet of the trochlea seemed involved; this prevented complete extension of the elbow. The bone surrounding the lesion showed normal structure.

A roentgenogram of the left elbow was negative.

On the third hospital day, the medial aspect of the lower end of the right humerus was exposed and incised; this revealed a cavity from which portions of soft, friable yellowish tissue and of soft, pinkish currant-jelly-like tissue were readily curetted. The cavity was thoroughly curetted, not packed with bone chips, and closed by approximation of the muscle layers. Microscopic examination of the material removed showed a benign giant-cell tumor. The patient was discharged on the sixth postoperative day.

*Second admission* (two and a half years later). The patient was followed in the Tumor Clinic, receiving three courses of roentgen-ray therapy, of 800 r each. There was a gradual increase of flexion deformity to about 65°. The patient, however, was able to work as a mechanic, not lifting much weight. He was readmitted to the hospital because there was some question of increase in size of the residual mass in the elbow.

On re-examination, the general physical condition was normal. The left elbow was held in 65° flexion. Extension was limited to 70°, and flexion was limited to 120°. Full and painless pronation and supination were possible. There was a circumscribed, bony hard swelling over the medial humeral epicondyle, which was firmly attached to the bone and tender in some areas. There was full ulnar-nerve function. The axillary lymph nodes were not enlarged.

The temperature, pulse, respirations and blood pressure were normal.

Examination of the blood and urine was essentially as before. The blood calcium was 10.6 mg. and the phosphorus 3.2 mg. per 100 cc.; the phosphatase was 2.9 Bodansky units.

A roentgenogram of the chest showed some emphysema and pulmonary fibrosis, but no metastatic lesions. A roentgenogram of the right elbow showed no definite increase in the size of the lesion.

On the tenth hospital day, an operation was performed.

## DIFFERENTIAL DIAGNOSIS

DR. CHANNING C. SIMMONS: This man had some bone condition of the lower end of the humerus. There are many things to be considered, but roughly these bone conditions can be divided into five categories: unusual conditions, such as a coccidioidal infection and an echinococcal cyst, which I have never seen, although they occur in other parts of the country; an ordinary inflammatory lesion, such as tuberculosis, syphilis or osteomyelitis; metabolic disease, parathyroid disease or primary disease of bone, such as Paget's disease; metastatic tumors; and primary bone tumors, either malignant or benign.

## CASE 28141

## PRESENTATION OF CASE

*First admission.* A thirty-five-year-old Russian butcher's helper was admitted to the hospital because of pain and disability in the right elbow for one month.

A year before entry, the right elbow was slammed by the door of an auto in which the patient was riding. There was considerable local pain at the time, but no swelling, discoloration or actual disability was noted. Since then, he had experienced occasional slight pain along the inner aspect of the elbow. In the month before entry, the pain tended to become severer, and he was unable to straighten the elbow fully. There were no constitutional symptoms.

On admission, the patient appeared thin and pallid. There was a smooth, rounded swelling over the internal condyle of the right humerus, enlarging this landmark to about twice its normal size. The skin overlying this mass was not at tached, or otherwise altered. The mass was tender posteriorly only (in the region of the ulnar nerve). Extension was limited by about 20°, but other movements were normal. There was no evidence of interference with the ulnar nerve. The other extremities were normal, and the rest of the physical examination was negative.

The temperature, pulse, respirations and blood pressure were normal.

Examination of the blood showed a red cell count of 4,800,000, and a white cell count of 10,500 with 72 per cent polymorphonuclears. The blood calcium was 11.0 mg., and the phosphorus was 3.3 mg per 100 cc.; the phosphatase was 3.4 Bodansky units. The blood Hinton reaction was negative. The total cholesterol was 114 mg. per 100 cc.

A roentgenogram showed a multilocular cystic area in the medial condyle of the right humerus. The bone appeared thickened anteriorly, without interruption of the cortex. The upper aspect of the facet of the trochlea seemed involved; this prevented complete extension of the elbow. The bone surrounding the lesion showed normal structure.

A roentgenogram of the left elbow was negative.

On the third hospital day, the medial aspect of the lower end of the right humerus was exposed and incised; this revealed a cavity from which portions of soft, friable yellowish tissue and of soft, pinkish currant-jelly like tissue were readily curetted. The cavity was thoroughly curetted, not packed with bone chips, and closed by approximation of the muscle layers. Microscopic examination of the material removed showed a benign giant-cell tumor. The patient was discharged on the sixth postoperative day.

*Second admission* (two and a half years later). The patient was followed in the Tumor Clinic, receiving three courses of roentgen ray therapy, of 800 r each. There was a gradual increase of flexion deformity to about 65°. The patient, however, was able to work as a mechanic, not lifting much weight. He was readmitted to the hospital because there was some question of increase in size of the residual mass in the elbow.

On re-examination, the general physical condition was normal. The left elbow was held in 65° flexion. Extension was limited to 70°, and flexion was limited to 120°. Full and painless pronation and supination were possible. There was a circumscribed, bony, hard swelling over the medial humeral epicondyle, which was firmly attached to the bone and tender in some areas. There was full ulnar nerve function. The axillary lymph nodes were not enlarged.

The temperature, pulse, respirations and blood pressure were normal.

Examination of the blood and urine was essentially as before. The blood calcium was 10.6 mg and the phosphorus 3.2 mg per 100 cc., the phosphatase was 2.9 Bodansky units.

A roentgenogram of the chest showed some emphysema and pulmonary fibrosis, but no metastatic lesions. A roentgenogram of the right elbow showed no definite increase in the size of the lesion.

On the tenth hospital day, an operation was performed.

## DIFFERENTIAL DIAGNOSIS

DR. CHANNING C. SIMMONS. This man had some bone condition of the lower end of the humerus. There are many things to be considered, but roughly these bone conditions can be divided into five categories: unusual conditions, such as a coccidioidal infection and an echinococcal cyst, which I have never seen, although they occur in other parts of the country; an ordinary inflammatory lesion, such as tuberculosis, syphilis or osteomyelitis; metabolic disease, such as Paget's disease; metastatic tumors; and primary bone tumors, either malignant or benign.

The first category, the unusual bone conditions, can probably be excluded, although at one time I made a list of forty-five different conditions that I have seen erroneously diagnosed as osteogenic sarcoma. The inflammatory conditions—tuberculosis, syphilis and osteomyelitis—must be considered. The joint was not involved. There was no evidence of tuberculosis elsewhere. The blood Hinton reaction was negative. Osteomyelitis is not suggested by either the physical examination or the laboratory findings. Metabolic disease may be well ruled out, for the blood chemical findings were normal, and there was no evidence of any disease of the other bones. The general physical examination was not remarkable, except that the patient was a rather slender man.

So far as metastatic tumors are concerned, there is no evidence of any tumor as a primary source of metastases. This condition had existed for three and a half years since the onset. The duration was one and a half years at the first admission, and the second admission was two and a half years later.

That brings us down to a primary tumor, either benign or malignant. A history of trauma is obtained in about 40 per cent of the cases of primary bone tumors. I think it is fairly safe to say that the tumor in this case was not malignant, for a malignant bone tumor would give some evidence of remote metastases three and a half years after onset. Giant-cell tumors often appear after injury in the humerus and in the knee. In the femur, they are apt to arise in the inner condyle; in the humerus, in the outer condyle. They originate in the medulla, cause bone destruction, extend to the cartilage, as this one did, without breaking through into the joint, and form an expanding bone tumor.

This x-ray film, I take it, is an early one. The outline of the periosteum is unbroken except at one point. There is some expansion in this other film. The gross description of the tumor removed at the first operation is certainly compatible with that of a giant-cell tumor.

These tumors appear in two forms: a currant-jelly-like, very vascular tissue, and fibrous tissue that is yellow in color, probably owing to deposits of hemosiderin and lipid material. Following the first operation, the patient received x-ray treatment with no appreciable improvement, and he re-entered with essentially the same condition—a little more advanced. The second x-ray film shows bulging of the internal condyle down to the joint surface. I think that the limitation of motion was partly due to mechanical interference.

My diagnosis in this case is giant-cell tumor. Such tumors are cured at times by excision or

curettage, at times by radiation; in a study of a large series, about 30 per cent of the patients were not cured by either method and came eventually to amputation. About 7 per cent undergo malignant change. As I have seen these cases, the defect never fills up with normal bone, and if bone chips are placed in the cavity after curetting they are absorbed. My diagnosis is giant-cell tumor, running the course that many of them do.

DR. TRACY B. MALLORY: You would not be seriously worried over the possibility of malignant tumor?

DR. SIMMONS: No; I should not.

#### CLINICAL DIAGNOSIS

Giant-cell tumor, right elbow.

#### DR. SIMMONS'S DIAGNOSIS

Giant-cell tumor of humerus.

#### ANATOMICAL DIAGNOSIS

Giant-cell tumor of humerus.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: This lesion was once again curetted, and the gross material on this occasion was rather fibrous, with many yellow spots in it. It did not show any of the currant-jelly appearance. On microscopic examination, there are areas of quite characteristic giant-cell tumor. These are interspersed with areas of rather dense fibrosis in which a good many cholesterol-filled foam cells are found. There are a few trabeculae and osteoid material, but nothing that suggests malignant lesions. I suspect that the unusual degree of fibrosis could perhaps be attributed to the x-ray treatment that the patient had received off and on during this period.

DR. SIMMONS: I think that is the usual story—increase in fibrosis following either curettage or x-ray treatment. The cavity never fills in with normal bone.

DR. GEORGE W. HOLMES: I should like to know, although I was present at the time this question of operation was discussed, just why they operated. I presume that it was to improve function, and I wonder if operation would improve function, because there is nothing in the lesion as I see it in the x-ray film to make me think of a malignant tumor; as a matter of fact, it really did improve somewhat under radiation. The outlines are sharp, it has not grown any in two years, and although it has not filled in with new bone, it is at least quiescent.

DR. MALLORY: The patient, who was a manual worker, had considerable limitation of function and found it difficult to work.

DR. GEORGE W. VAN GORDER: After considerable discussion in the Tumor Clinic and in the Orthopedic Staff, it was decided that the wisest operative procedure to carry out on this patient's arm was excision of the tumor, in addition to an arthrodesis of the elbow joint, allowing the radial head to remain free to rotate in a normal way on the remaining external condyle of the humerus.

The reason that a movable elbow joint was not considered advisable was that the tumor occupied too great a portion of the articular surface to allow for normal motion or stability after its excision. In other words, more than half the articular surface of the lower end of the humerus would have had to be sacrificed, and this would have resulted in a useless joint. An alternative was to perform a complete excision of the lower end of the humerus, but this would also have involved too great a portion of bone to permit any future stability or strength in the joint. Since this patient is the father of a family and has to work, and since he could not do his work with a flail elbow, it was decided that a firm ankylosed joint in an optimal position of election would be the most satisfactory answer to his problem from an economic and social point of view. The patient was asked about the type of work that he performed and the angle at which his elbow was most useful in carrying on his job, the idea being that if the joint were solidly fused at the proper angle, it would later be of the greatest service to him. These matters were all considered before the operative procedure was carried out.

In the surgical procedure itself, the tumor was completely excised, and following excision, the cartilaginous surface of the ulna and its adjacent humeral articular surface were removed, after which a long vitallium bone plate, which had previously been bent at the proper angle, was applied to the posterior aspect of the joint, with three screws to hold it to the lower end of the humerus and with three screws to the shaft of the ulna.

Following application of this plate, the elbow joint seemed to be firm and in its proper position, and the upper end of the radius was not interfered with at all, so that full rotation of the forearm remained undisturbed. Two drill holes, each 6 mm. in diameter, were then made through the external condyle of the humerus across the joint line into the ulna, and into these drill holes two tibial bone grafts were driven, which acted as dowels, anchoring the two bones together. A third bone graft was placed between the humerus and ulna in another direction, avoiding the radiohumeral articulation.

The wound was then closed, in the hope that solid union would take place between the ulna and external condyle of the humerus and that ro-

tation motion would be preserved for the forearm. Should this result be obtained, the patient will be able to continue his job or at least do heavy work with a very useful arm.

## CASE 28142

### PRESENTATION OF CASE

A thirty-year-old housewife was admitted to the hospital because of a mass in the upper jaw.

The patient was well until six months before entry, when, in the fifth month of an otherwise normal fifth pregnancy, she noted a slightly painful gray, purulent swelling on the upper jaw, where a tooth had been extracted several years previously. Two weeks later, a smooth, firm, slightly painful lump appeared at the same site on the buccal side of the jaw. It grew rapidly for a month, and then it was excised in another hospital. Following this, there was a recurrence of the lesion, with spread over a larger area of the jaw. The mass was re-excised in the other hospital on two subsequent occasions. The pathological diagnosis each time was epulis. Following the last excision, two months before entry, the mass became so large that the patient had trouble in closing her mouth, and in chewing her food. At times, there was a dull ache in the jaw, with occasional radiation to the neck. There was no pain elsewhere. The pregnancy terminated in normal delivery two weeks before entry.

The past history was noncontributory. Four earlier pregnancies had resulted in two miscarriages and two living children. The family history was irrelevant.

On admission, the patient appeared well developed and nourished. The left cheek was distended by a firm mass, extending from the midline near the nose back to within 2 cm. of the ear, and from below the eye down to the mandible. The left nostril was not obstructed. Just under the lip, the lower edge of the mass was denuded of epithelium, appearing yellow brown with spots of old blood. Within the mouth, the swelling approached the midline of the hard palate, irregularly. The buccal aspect of the left maxilla was occupied entirely by the mass. The swelling was moderately tender. Both tonsils were enlarged, and an apparent lymph node was palpable, in the left supraclavicular region. The spleen was questionably palpable, and there was moderate suprapubic tenderness. Pelvic examination showed normal puerperal changes. General physical examination was otherwise negative.

The blood pressure, temperature, pulse and respirations were essentially normal.

Examination of the blood and urine was essentially negative. The blood calcium was 10.4 mg.

and the phosphorus 3.4 mg. per 100 cc., and the phosphatase was 3.5 Bodansky units.

Roentgenograms of the jaw showed an area of destruction in the left maxilla extending from the spinous process and the midline back to within 0.5 cm. of the posterior margin. The involved bone appeared moth-eaten and almost completely destroyed. The apexes of the bicuspids, cuspids and lateral incisor were involved. A large soft-tissue mass extended beneath the lip and cheek, including several fine bone spicules. There was an apparent bulge into the left maxillary antrum. This cavity was enlarged in all directions, and its wall appeared broken through in several places. A roentgenogram of the chest was negative.

A biopsy of the mass was taken on the second hospital day, and a week later an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. HAROLD G. TOBEY: This is a rather short history of what apparently was a malignant tumor. We can probably rule out acute or chronic infection of the sinuses. The entire history was too short for any chronic infection, except possibly an osteomyelitis, which might develop as quickly as this, but probably would not. The only specific infection we must consider is the possibility brought up by the yellow-brown spots, particularly the yellow, which might suggest actinomycosis. There is no bacteriologic report; presumably, that was thought of and ruled out. Here again, six months is a rather short time for such a rapid spread, even of actinomycosis. So that we are brought down to the possibility of a malignant growth.

The alveolar process and the sinuses are subject to the usual malignant growths, carcinoma and sarcoma, and at times some of the lymphomas. It is significant that a few years previously a tooth had been extracted, and the tumor presumably occurred at the site of this tooth. The tumor was removed, and a diagnosis of epulis was made. It is possible that the diagnosis was incorrect. The ordinary epulis presents a picture similar to that of a benign giant-cell tumor of bone, but sarcomatous "degeneration" of the latter is conceivable. The recurrence happened in exactly the same place where the mass had been removed. So far as epithelioma is concerned, it is usually much more slowly progressing. It may start inside the antrum, possibly where the tooth was extracted. The fact that both tonsils were enlarged makes me think of the possibility of lymphoma, but there was practically no adenopathy. One lymph node was palpated in the left supraclavicular region, but nothing is said about palpation of lymph nodes elsewhere.

May we see the x-ray films?

DR. GEORGE W. HOLMES: These two small films show the extent and character of the lesion better than any of the others. It is quite large, moderately dense, and, what is most important, shows spicules of bone within the tumor substance. It has partially destroyed the antrum, and there is bulging of the bone, which is a little unusual. A rapidly growing malignant tumor does not as a rule cause bulging, but simply destroys the walls. This has done both. It is essential to know whether the floor of the orbit is destroyed or not. We thought it was at least infiltrated by this growth and partially destroyed. This tumor has some of the characteristics of benign tumor and some of the characteristics of a malignant tumor. I think it would be fair to say that it would be very difficult to explain the infiltration of bone and the presence of spicules in a benign lesion.

DR. TOBEY: The benign lesions usually expand the bone, and the bone is absorbed by pressure.

There is a tumor called a "pregnancy tumor," which I have never seen and know nothing about, but it does occur about the alveolar processes.

There are other conditions that might be considered; one of them is mucocoele of the sinus, which is more common in the frontal sinus, with destruction of the bone and smooth surfaces, but this is altogether too rapidly growing for a mucocoele. In the absence of any acute infection and in view of the involvement and active destruction of the bone, I should say that this tumor was probably an osteogenic sarcoma.

DR. CHANNING C. SIMMONS: I saw this woman, and the question of whether this was a pregnancy tumor arose. I reviewed two articles on the subject, and the largest pregnancy tumor reported was 1.5 cm. in diameter. I also talked with some of the dental surgeons about pregnancy tumors of the mouth, and was told that a shaggy appearance of the mucous membrane over the alveolar process was not uncommon. This tissue is very vascular, but it usually disappears after delivery. I have also seen angiomas about the mouth and elsewhere that increased in size during pregnancy and went down afterward. There is apparently some metabolic disturbance that makes them grow. This particular tumor was a new growth of either sarcomatous or possibly adamantinomatous type; but it was very rapidly growing for the latter. The other thing I might say is that a tumor with a histologic picture such as this, if it occurred in the long bone, would probably cause death with metastasis, but in the jaw such tumors do not often metastasize.

A PHYSICIAN: What about ossifying fibromas?

DR. SIMMONS: I have never seen one. I have

seen diffuse fibromas of the upper jaw, where the antrum is thickened and the whole upper jaw transformed into rather soft ossifying tissue. They apparently arise from the inner process of the superior maxilla and fill the antrum.

DR. HOLMES: They cause a much denser shadow than this one did, and completely obliterate the entire area of the sinus.

DR. SIMMONS: They are slowly growing tumors and occur in patients of about ten to fifteen years of age.

DR. LANGDON PARSONS: The last biopsy taken from the tumor itself was reported as ossifying fibroma. When the entire maxilla was removed and the specimen in the pathologist's hand, the report was still ossifying fibroma. So far as the orbital floor was concerned, it was completely destroyed. This tumor had definitely grown under observation in the week that the patient spent on the wards.

DR. SIMMONS: Was it encapsulated?

DR. PARSONS: Yes, except for the part that had broken into the orbit.

DR. TOBEY: Is that not quite fast for sarcoma? It suggests a rapidly growing lymphoma.

DR. SIMMONS: Do you think that the pregnancy had anything to do with the rapidity of growth?

DR. TRACY B. MALLORY: I do not know the answer to that. One suspects it, of course. Pregnancy can influence the growth of a variety of tumors.

#### CLINICAL DIAGNOSIS

Ossifying fibroma of maxilla.

#### DR. TOBEY'S DIAGNOSIS

Osteogenic sarcoma of maxilla.

#### ANATOMICAL DIAGNOSIS

Osteogenic sarcoma of maxilla.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The early biopsies on this tumor were all rather inadequate, and for that reason the diagnosis was not made sooner. The final specimen showed undifferentiated, anaplastic cells embedded in osteoid tissue, and on a histologic basis one could not call it anything but an osteogenic sarcoma.

What the outlook is I do not know. As Dr. Simmons said, tumors in this area often behave more benignly than their histologic characteristics lead one to predict, so that it is possible that the patient has been cured and will not have a metastasis. Had this tumor occurred in a long bone, I should not hold out any hope whatever.

DR. HOLMES: Did the patient have any radiation?

DR. PARSONS: She had had some before she came here. We were never able to find out how much.

DR. MALLORY: The immediate results of operation were excellent. It was possible to excise all the visible tumor, and in spite of the fact that there is no floor to the orbit, the eye is not sagging and the vision is good.

## EARLY RISING AFTER OPERATIONS

THE supposed necessity of keeping patients in bed for a more or less arbitrary minimum period of about a week and in the hospital for ten days after many of the less severe major operations not associated with prostrating illness has recently been questioned in several countries.<sup>1-4</sup> Leithäuser and Bergo's<sup>1</sup> study of this subject presents data on 370 cases subjected to appendectomy and on 66 cases having had other operations. The study appears to prove that nothing harmful is likely to happen to these patients if they get out of bed on the day after operation. The authors even claim that this method of postoperative care gives excellent results, since there was not a single case with

pulmonary complications, dehiscence, postoperative hernia, thrombophlebitis or death. Their treatment really consists of a logical extension of certain ideas concerning the prevention of pulmonary complications that have recently been enthusiastically adopted by certain surgeons, although first proved valuable twenty-five years ago.<sup>5</sup> The late Dr. E. Amory Codman, of Boston, once expressed the opinion that the time would come "when interval and prophylactic appendectomy would be performed through a McBurney incision under local procaine anesthesia in the surgeon's office, and the patient would be allowed to go home a few hours later."<sup>6</sup>

The details of Leithäuser and Bergo's<sup>1</sup> treatment are as follows:

After operation the patients were turned frequently in bed and were instructed to be active and to take deep breathing exercises at regular intervals. On the first postoperative day, provided conditions were satisfactory, they were assisted in sitting on the edge of the bed [after assuming the right lateral position] and then in standing beside the bed for deep breathing exercises. [This consumed only a few moments.] While in each position they were instructed to take several deep inhalations and were urged to cough. This procedure seldom failed promptly to clear the lungs of accumulations of mucus. After this was accomplished they were permitted to walk about the room and to sit in a chair for a few moments, and then they returned to bed. On returning they sat on the edge of the bed and reclined on the right shoulder. These sitting-up and ambulatory exercises were always first carried out under the supervision of one of us. Such exercises were then repeated during the first postoperative day with the assistance of a nurse, and thereafter the patients were encouraged to increase their activities voluntarily. They left the hospital by automobile. . . .

It is unfortunate that no statement is made regarding the time of determination of the presence or absence of postoperative hernia, since many surgeons are skeptical of such findings unless systematic search has been made at least six months after operation. It goes without saying that the authors' method of suturing wounds, in which No. 0 chromic catgut and steel wire or nylon were employed, was eminently satisfactory.

The average duration of confinement to bed of the appendectomy patients was 1.5 days: 75 per

cent of them arose on the first day, 12 per cent on the second, and 8 per cent on the third. The average stay in the hospital was 2.3 days: 37 per cent of the patients left on the first day, 32 per cent on the second, 14 per cent on the third, and 10 per cent on the fourth. These figures are extremely interesting and significant, and bear comparison with those of similar cases treated according to more orthodox methods. For example, in the months of March and September, 1941, of 39 ward and 267 semiprivate patients who held policies issued by the Massachusetts Hospital Service (Blue Cross) and who were operated on for appendicitis (all types), the total stay in the hospital averaged 10.6 and 12.5 days, respectively.<sup>7</sup> Furthermore, according to the statements of six prominent Boston surgeons,<sup>8</sup> the average time for the earliest getting-up of their private and ward patients with simple appendectomies is 5.7 days, with an average time of 6.7 days for all cases, and the average time for the earliest discharge from the hospital is 8.3 days, with a slightly higher average for all cases.

From these data, it is evident that an appreciable difference exists between the times of the cases treated by Leithauser and Bergo and those given the usual postoperative care. One might argue that patients should be allowed to get up one or two days earlier without further ado, thereby saving that much time in the hospital. Many believe, however, that such a procedure might not be so safe as really early rising, because it is likely that most wounds are stronger on the first and second days after operation than they are for the following week, owing to the well-known "lag period" in healing and the gradual weakening of certain suture material. In any event, it is possible that great savings in complications, let alone costs, would arise following the general adoption of the early-rising technic. It would be well worth while for others to experiment along this line.

#### THE CONTROL OF CANCER

IN times when practically the total effort of this country is aimed toward a destruction of the young and healthy men of other countries, it seems almost useless to attempt to maintain interest in cancer control. However, regardless of war and sudden death, cancer will continue to make its inroads, sometimes taking the most useful and productive minds from the community. Because of the character of the disease itself and its high rate of mortality, there are few maladies that can compete with it from the standpoint of economic loss. Hence, even in these days, the medical profession, with its continuous contacts with the victims of cancer, should keep in mind the menace of this disease and the value of its control. In addition to their heavy emergency obligations, physicians must not forget this ever-present threat to life and happiness. Of special importance are the detection and cure of early cases of cancer, to lessen the burden on the hospital facilities of the community that is made all too heavy by the advanced or terminal cases of the disease.

In the past, notable gains in cancer control have been made in Massachusetts, and the American Society for the Control of Cancer is doing much throughout the country to check the advancing mortality from this disease. Ignorance, fear and procrastination should not be permitted to turn curable cases of cancer into hopeless ones.

For the past few years, April has been designated as "Cancer Month" by proclamation of the President. In the pressure of world events, this designation seems about as futile as a last year's newspaper, but just as the lesson to be learned from last year's newspaper was there for all to see, the knowledge of what should be done to control cancer is almost as plainly written, and fully as easily forgotten.

## MEDICAL EPONYM

## NEISSER'S DIPLOCOCCUS

Albert Neisser (1855-1916), when he was an assistant in the dermatologic clinic at the University of Breslau, published his paper "Über eine der Gonorrhoe eigenthümliche Micrococcusform [A Form of Micrococcus Peculiar to Gonorrhea]" in the *Centralblatt für die medicinischen Wissenschaften* (17:497-500, 1879). A portion of the translation follows:

If gonorrheal pus is spread as thinly as possible on a glass slide after Koch's method, allowed to dry and stained by simply flooding with an aqueous solution of methyl violet, and dried again, examination of the preparation under high power with the light cut down as little as possible will show at first glance, in addition to the dark violet-blue and variously shaped nuclei of the pus cells (the protoplasm of which is also stained, but only faintly), a number of more or less abundant clumps of micrococci. These have a quite characteristic and promptly recognizable typical form. . . . Nearly always two micrococci are seen lying close together—so closely that they give the impression of a single organism which is roll-shaped or biscuit-shaped, resembling a figure eight.

CASE HISTORY: CURETTAGE CAUSING  
PERFORATION OF THE UTERUS AND FATAL SEPSIS

Because of continued bleeding, a thirty-year-old primipara entered the hospital twenty-five days after the delivery of a stillborn baby. The past history was irrelevant. There was no evidence of previous illness. The heart, lungs and blood pressure were said to have been normal. There is no record of a blood examination at the time of admission, and no description of the patient's labor. On admission, a curettage was performed, and in the process the uterus was perforated at the junction of the internal os and the anterior wall. According to the record, no intestine was brought down or injured. As soon as it was appreciated that the uterus had been perforated, the operation was stopped, and a gauze strip was placed in the perforation. The patient ran a septic course for three weeks. At the end of this time, the temperature reached normal and remained so for a week, when transfusion was performed. There is no evidence in the record of the blood picture that justified this transfusion. The transfusion itself was followed by a slight febrile reaction but the patient was sent home the following day. She remained in bed at home for

a week, re-entered the hospital, and died of fulminating septicemia in less than twenty-four hours.

*Comment.* It is unfortunate that the record does not give more specific details of the delivery and subsequent convalescence. It is quite possible that the continued bleeding was caused by some small piece of placenta, which may have been adherent and may have had to be removed manually at the time of delivery. It is probable that this patient had fever before she entered the hospital; in that event, invasion of the uterus, unless the hemorrhage was profuse, was contraindicated. The fever, which is reported to have followed the curettage, in all probability meant that the uterus was harboring a low-grade infection at the time of entry and that the operative procedure of curettage broke down Nature's defensive wall and resulted in a spread of infection that demonstrated itself in the fever, which lasted for three weeks. It is quite probable that the perforation of the uterus was an incident and had nothing to do with the final outcome. During the week that the patient was home in bed, the history does not tell whether or not the temperature was normal, but it probably was not. The transfusion must have been given because of a low red-cell count and possibly for the purpose of stimulating recovery from the anemia associated with infection. In itself, the transfusion could not have precipitated the ultimate septicemia.

This case illustrates primarily the seriousness of curetting any patient with a temperature following childbirth as well as, of course, following abortion. The uterus in such a case should be left absolutely alone except in the presence of frank hemorrhage, when intrauterine manipulation should be conducted in the gentlest fashion, preferably with the finger.

## COMMITTEE TO REVISE THE BY-LAWS

The following is the revised copy of the by-laws of the Society that will be presented by the Committee to Revise the By-laws to the Council for approval at its special meeting on April 15.

J. HARPER BLAISDELL, *Chairman*  
CARL BEARSE, *Secretary*  
JOHN FALLON  
HAROLD R. KURTH

## CHAPTER I

## FELLOWSHIP

*Section 1.* Applicants for fellowship in the Massachusetts Medical Society are required to satisfy the censors that they are not less than twenty-one years of age; that they are of sound mind and of good

5 character, that they have a Baccalaureate or Do-  
 10 torate of Medicine from a medical school approved  
 by the Council, or have received the approval of the  
 Committee on Membership, that they have received  
 a license to practice medicine within the United  
 States or its territories, that they do not practice  
 medicine in a manner contrary to the code of ethics  
 of the Society, that they have made application  
 according to the provisions of Chapter V, and  
 15 that they have paid the examination fee of three  
 dollars

They shall appear personally before the censors  
 and satisfy them that the above requirements are  
 fulfilled

*Section 2* Applicants found to be so qualified  
 shall, on paying the assessment for the current fiscal  
 year (except as hereafter provided in Section 6  
 5 of this chapter) and subscribing to the by laws and  
 code of ethics, all within two weeks from the date  
 of their examinations, be approved by the censors

They furthermore shall, on confirmation by the  
 president and by the secretary of the Society, be  
 admitted fellows of the Society and shall receive  
 10 certificates of fellowship in testimony thereof signed  
 by the President and by the Secretary

*Section 3* Fellows having a legal residence in  
 Massachusetts shall be known as resident fellows  
 all others, as nonresident fellows

Nonresident fellows shall receive the official pub-  
 5 lications of the Society and may attend Society  
 meetings, but may not vote, hold office or receive  
 protection under the medical defense act of the  
 Society

*Section 4* Honorary fellowship may be conferred  
 on distinguished members of the medical profes-  
 sion

Associate fellowship may be conferred on eminent  
 5 workers in the allied sciences

Such fellowships may be conferred by a two-thirds  
 vote of the Council at a stated meeting, provided  
 10 written nominations therefor have been submitted  
 by two or more fellows at a previous stated meet-  
 ing and have been approved by the Committee on  
 Membership

Honorary and associate fellows may attend and  
 address meetings of the Society, but shall not be  
 15 accorded other rights or privileges, or be subject  
 to assessment

*Section 5* Fellows who are sixty five years of age  
 or older whose assessments have been paid or re-  
 mitted may, by vote of the Executive Committee,  
 5 acting on recommendation of the Committee on  
 Membership, become retired fellows

They shall be in good standing, and may attend  
 and address meetings of the Society, but shall not  
 be accorded other rights or privileges, except that,  
 10 on request annually, they shall receive the publica-  
 tions of the Society

They shall not be subject to assessment  
 Applications for retirement shall be addressed to  
 the Executive Committee and sent to the Treasurer

Retired fellows may, on their own request, be  
 15 restored to active fellowship by the Executive Com-  
 mittee.

*Section 6* Fellows shall be assessed such sums  
 as are voted by the Council, and such additional  
 sums as are voted by the district societies for their  
 own use

5 The fiscal year shall begin on the first day of  
 January Assessments shall be paid in advance  
 The first assessment paid by a fellow admitted to  
 the Society following the December examinations  
 shall cover his dues for the succeeding fiscal year  
 10 and shall be the amount fixed for that year

Assessments may be remitted by the Executive  
 • Committee on recommendation by the Committee  
 on Membership

Whenever a fellow owing more than one annual  
 15 assessment pays in part, the payment or payments  
 so made shall be considered as on the assessment  
 or assessments longest due and for no others

*Section 7* Resignations shall be submitted in  
 writing to the Treasurer, who shall deliver them  
 to the Committee on Membership

This committee shall submit them with recom-  
 5 mendations to the Executive Committee for action

Resignations shall be accepted only from fellows  
 whose assessments have been remitted or paid in full

*Section 8* Fellows who despite notification by  
 registered letter from the Treasurer, have not paid  
 assessments for two years, or who, despite notifica-  
 5 tion by registered letter from a district treasurer,  
 have not paid the assessments of their district society  
 for two years, shall be deprived of the privileges  
 of fellowship by the Executive Committee, acting  
 on a report of the Committee on Membership,  
 unless otherwise ordered

*Section 9* Fellows who have been convicted in  
 a court of law of a crime involving moral turpitude  
 or who have been guilty of attempts to harm the  
 Society or to injure its usefulness, of advertising  
 5 nostrums for sale or otherwise offering them to the  
 public, or professing to cure disease by secret meth-  
 ods, of gross violations of these by laws, of the code  
 of ethics of the Society or of the American Medical  
 Association, of presenting false certificates or false  
 10 statements of character or of educational require-  
 ments of accepting rebates on prescriptions or ap-  
 pliances, or of any other conduct unbecoming a  
 physician, may be expelled from the Society or  
 otherwise disciplined as provided in Chapter VIII,  
 15 Section 9

A fellow who has been deprived of his license  
 to practice medicine in the Commonwealth shall  
 automatically cease to be a fellow of the Society

*Section 10* Former fellows who desire to be  
 readmitted following retirement, resignation not  
 requested by the Committee on Ethics and Disci-  
 5 pline, or deprivation of fellowship for arrears shall  
 make application in writing addressed to the Execu-  
 tive Committee and sent to the Secretary

Such applications shall be referred for investiga-  
 10 tion to the board of membership of the district  
 society concerned, which shall report with recom-  
 mendations to the Committee on Membership

This committee shall report with recommenda-  
 tions to the Executive Committee

The Executive Committee may readmit former  
 fellows so recommended

*Section 11* Committees living under considera-  
 tion the applications of former fellows (a) whose  
 resignations have been requested by the Committee  
 on Ethics and Discipline or (b) who have been

- 5 deprived of fellowship under the terms of Section 9 shall consult with the Committee on Ethics and Discipline before reporting their recommendations to the Council.

## CHAPTER II

### MEETINGS OF THE SOCIETY

*Section 1.* The annual meeting of the Society shall be held in Boston, on the second Wednesday of June, unless otherwise ordered by the Council.

- 5 The order of business shall be: (1) reading of the record of the last annual meeting; (2) report by the Secretary of changes in membership during the year; (3) report by the President on the state of the Society; (4) such other business as may lawfully come before the meeting; (5) annual oration.

*Section 2.* Special meetings of the Society may be called by the President, or by vote of the Council, and shall be called on written request by ten councilors or one hundred fellows.

*Section 3.* The deliberations of the Society shall be governed by parliamentary usage as interpreted by *Roberts' Rules of Order*, when not in conflict with the by-laws of the Society.

- 5 One hundred fellows shall constitute a quorum.

## CHAPTER III

### DISTRICT SOCIETIES

*Section 1.* The boundaries of district societies may be changed, and new districts may be established, by the Council.

*Section 2.* The membership of each district society shall consist only of such fellows, whether active or retired, as have legal residences within the boundaries of the district, except in cases decided otherwise by vote of the Executive Committee.

- 5 *Section 3.* Any fellow wishing to transfer membership from one district society to another without a change of legal residence must so petition the Committee on Membership in writing, stating his reasons therefor.

The Committee on Membership shall report, after consultation with the officers of the two districts concerned, its recommendations to the Executive Committee for action.

*Section 4.* Each district society may adopt by-laws and regulations for the government of its own affairs and levy assessments, provided such by-laws and regulations are not in conflict with those of the Society.

*Section 5.* Each district society shall hold its annual meeting between the fifteenth day of April and the fifteenth day of May.

- 5 Each district society at this meeting shall elect by ballot from its active fellows: a president, who shall be *ex officio*, a vice-president of the Society; a vice-president; a secretary; a treasurer; councilors as below specified; four censors; a supervising censor; a commissioner of trial; a member of the Committee on Public Relations; a member of the Committee on Legislation; a member and alternate member of the Committee on Nominations.

- 15 Councilors shall be elected in number equal to one for every twenty active and retired fellows and a majority fraction thereof, as of the first day of January preceding.

Only councilors shall be eligible as supervising censors and members of the Committee on Public Relations and the Committee on Legislation.

- 20 Only councilors who have held this office for at least one year shall be eligible as members of and alternates to the Committee on Nominations. Members of and alternates to the Committee on Nominations shall not serve for more than five consecutive years and shall not be eligible for re-election for three years thereafter.

- 25 Only fellows who have been members of the Society for at least ten years shall be eligible as censors or supervising censors. The term of the supervising censors shall be five years. They shall not immediately succeed themselves. All supervising censors shall have been censors previously.

- 30 Councilors, censors, supervising censors, members of the Committee on Public Relations, members of the Committee on Legislation, members of the Committee on Nominations, and commissioners of trial shall take office at the close of the next annual meeting of the Society.

- 40 The councilors of each district society shall meet on call by the secretary at or as soon as possible after the annual meeting of the district society and elect two of their number to serve as member and alternate of the Executive Committee, in accordance with Chapter VII, Section 2.

- 45 Members of and alternates to the Executive Committee shall serve for three years and shall not be eligible for re-election for three years thereafter.

- 50 The term of office of the alternate shall be concurrent with the term for which the member was elected.

Vacancies that occur during the term of office of such member or alternate shall be filled promptly by vote of the councilors of the district concerned *ad interim*.

*Section 6.* The secretary of each district society promptly after its annual meeting, shall report on appropriate forms, to the Secretary the names and residences of fellows elected, as provided in Chapter III, Section 5.

He shall promptly notify the Secretary, on the required form, of deaths of fellows in his district.

He shall also perform such duties as are defined in Chapter V.

- 10 He shall call, at or as soon as possible after the annual meeting of the district society and before the annual meeting of the Society, meetings of the district councilors to elect the member and alternate of the Executive Committee, and shall send to the Secretary the names of the member and alternate chosen.

He shall see that a new member or alternate is chosen in a similar manner to fill a vacancy as it occurs, as provided in Section 5.

*Section 7.* The treasurer of each district society shall collect the assessments of his district.

- 5 He shall furnish a list of fellows two years in arrears to the Committee on Membership for action as provided in Chapter I, Section 8.

## CHAPTER IV

### THE COUNCIL

*Section 1.* The Council shall consist of councilors chosen by the district societies, the president, ex-presidents, president-elect, vice-president, vice-presidents *ex officio*, secretary, treasurer, and assistant.

5 treasurer of the Society the secretaries of the district societies and the chairmen of all standing committees

10 The Council each year shall hold three stated meetings in Boston, unless otherwise ordered by the Council. The annual meeting shall be held on the day next preceding the annual meeting of the Society. A stated meeting shall be held on the first Wednesday in October, and another, on the first Wednesday in February.

15 Special meetings may be called by the President by vote of the Council, or by the written request of ten councilors.

Section 2 The deliberations of the Council shall be governed by parliamentary usage as contained in *Roberts Rules of Order*, when not in conflict with the by laws of the Society.

5 Fifty councilors shall constitute a quorum.

Section 3 The Council at its annual meeting on nomination by the Committee on Nominations or from the floor, shall elect by ballot officers of the Society as follows: president elect, who shall serve as president elect until the second annual meeting of the Society after his election and shall unless otherwise voted by the Council become president on his installation in the course of that meeting serving thereafter as president until the installation of his successor, a vice president, secretary, treasurer, and assistant treasurer, all of whom shall assume the duties of office at the close of the annual meeting of the Society and shall hold office until their successors have been duly elected. Councilors only shall be eligible to the offices above named.

20 The Council in event of the death or the incapacity of the President Elect, shall elect a president by ballot, at its next annual meeting on nomination by the Committee on Nominations or from the floor.

25 The Council, at its annual meeting, on nomination by the Committee on Nominations or from the floor, shall elect by ballot a fellow to deliver an oration at the annual meeting of the Society the following year.

30 The Council at its annual meeting shall elect on nomination by the President Elect or from the floor, standing committees to serve for one year from the close of the annual meeting as follows: on Arrangements, on Publications, on Membership on Ethics and Discipline, on Medical Education on Public Health, on Medical Defense on Society Headquarters, on Finance, and on Hospital Relations.

Section 4 The Council shall elect at the stated meeting in October, on nomination by the President or from the floor, the Auditing Committee, composed of two fellows who are not councilors.

5 This committee, following the close of the fiscal year, shall require by a certified public accountant an examination of the assets and securities of the Society in the custody of the Treasurer, and of the Treasurer's books and accounts.

10 This committee shall verify the accountant's examination and report its findings at the stated meeting of the Council in February.

Section 5 The Council may at any meeting fill vacancies in office or elect committee.

Section 6 The Council may vote to establish or abolish sections for the consideration of scientific

papers at the annual meetings of the Society, and shall appoint the first chairman and secretary of a new section so established.

5 Each section shall elect annually a chairman and a secretary to serve for one year from the close of the annual meeting at which they are elected.

10 The duties of these officers shall be to arrange the programs of the meetings of their sections under the rules of the Council.

15 The chairman shall preside at the meetings of the section at the following annual meeting; the secretary shall take charge of the papers presented and shall transmit them promptly to the editor of the official journal of the Society.

Section 7 The Council shall on nomination by the President or from the floor, elect delegates to the House of Delegates of the American Medical Association in accordance with the by laws of that association.

It may, on nomination by the President or from the floor, elect delegates to such other medical meetings as it deems suitable.

Section 8 The Council shall vote the salaries of its officers and employees; the appropriations for its officers and committees, and such other appropriations as it deems suitable.

5 No officer or committee shall exceed the voted appropriation.

No salary to any officer or employee and no regular appropriation shall be increased except on recommendation of the Committee on Finance and by vote of the Council.

10 The Treasurer is authorized, on recommendation of the Committee on Finance, to pay such monies as may be necessary in the event of emergency the existence of which shall be determined by the President.

## CHAPTER V

### CENSORS AND SUPERVISING CENSORS

Section 1 The supervising censors shall constitute a Board which shall meet annually on the day appointed for the annual meeting of the Council. This board shall elect a chairman and also three of their members to sit with the Committee on Membership. Five supervising censors shall constitute a quorum.

10 The secretary of the Society shall act as secretary of the Board. He shall call special meetings at the request of the chairman or five supervising censors. He shall keep a permanent record of the proceedings of the Board and shall provide materials necessary for conducting examinations of applicants for fellowship.

15 The Board at its annual meeting shall adopt a uniform plan for the examination of applicants.

The supervising censors, on request, shall paid traveling expenses.

20 The supervising censors shall be chairmen of their respective boards of censors, and shall cause the examinations of applicants to be conducted in strict conformity to the plan adopted by the Board of Supervising Censors.

25 The censors of the several district societies shall meet for the examination of applicants semiannually on the first Thursday in May and on the first Thursday in December.

The approval of at least three censors shall be necessary to qualify an applicant.

30 An applicant failing two examinations may not again apply until three years have elapsed from the date of the last application.

Section 2. (a) The secretary of a district society may receive, *not later than* February 15 for the censors' examination in May or *later than* September 15 for the examination in December, an application for fellowship submitted on the proper form by an applicant whose legal residence is within the district of that society.

5 The secretary of the Suffolk District Society may receive, and officials of that society may act on, an application for nonresident fellowship.

The secretary of the district society shall verify each applicant's diploma and deliver his application to the Secretary *not later than* February 20 or September 20, respectively.

15 The official journal shall publish, in the first number on or after March 5 or October 5, a list of all applicants. This list shall include name, address, medical school and date of graduation of the applicant; name and address of the secretary of the district society concerned; and if a sponsor is required, the name and address of the sponsor.

20 Fellows are requested to send to the secretary of the district society concerned, *not later than*, respectively, March 20 or October 20, *confidential* written opinions on the qualifications of applicants.

(b) The secretary of a district society shall receive an application from a graduate of a discontinued medical school, a foreign medical school or any medical school not approved by the Council only when:

30 The applicant has possessed a license to practice medicine in the United States or its territories for at least five years;

35 The applicant has submitted with his application the name and address of a sponsor who is a fellow of the district society concerned; and

The sponsor has caused to be delivered by fellows of the Society to the secretary of the district society *confidential* written opinions on the qualifications of the applicant.

40 (c) The censors may admit to examination an applicant who is a graduate of a discontinued, foreign or unapproved medical school only when such applicant has been considered by the board of membership concerned and approved by the Committee on Membership.

The board of membership of a district society shall consist of the president, secretary and supervising censor.

50 It shall gather such information as it deems advisable to determine whether an applicant is conscientious, capable and reputable. It shall interview personally such applicant. It shall either approve or disapprove him for examination by the censors.

55 The secretary of the district society shall deliver to the chairman of the Committee on Membership, *not later than*, respectively, April 1 or November 1, all pertinent correspondence and other data together with the record of such applicant's approval or disapproval, with reasons therefor, by the board of membership.

The Committee on Membership shall have custody of such documents so long as needed and then shall

65 deliver them to the custody of the Secretary; they shall remain *confidential*.

The Committee on Membership shall consider the application of each applicant approved for censors' examination by a board of membership. It shall determine finally whether or not such applicant may take that examination.

70 The Committee on Membership shall not consider the application of any applicant disapproved by a board of membership except on the written request of a majority of that board of membership.

75 Decisions on applications by the Committee on Membership shall be final, and shall remain in force for two years.

80 The Committee on Membership shall notify the secretary of the district society concerned and each applicant considered of its decision *not later than*, respectively, April 20 or November 20.

Section 3. The secretary of each district society shall be the secretary of the district board of censors.

He shall furnish applicants with forms adopted by the Board of Supervising Censors.

5 He shall keep a record of all applicants for fellowship, and see that each applicant pays the examination fee of three dollars, that this fee is sent *promptly* to the Treasurer, that each successful applicant subscribes to the by-laws and code of ethics and within two weeks pays the assessments for the current year.

He shall furnish each new fellow with a copy of the *Digest, By-laws, Code of Ethics, and Medical Defense Act* of the Society.

15 He shall present, on the proper form and promptly after each examination, a bill to the Treasurer for censors' services, together with a list of all applicants examined.

20 The secretary of each district society shall fill out, sign and deliver promptly to the Secretary certificates stating that the successful applicants have complied with the requirements of the by-laws.

Section 4. The censors and secretaries shall be paid from the funds of the Society three dollars for each applicant examined. The amount paid shall be divided equally among those officers attending and taking part in the examinations.

## CHAPTER VI

### OFFICERS

Section 1. The President shall preside at the meetings of the Society, of the Council, of the Executive Committee and of the Committee on Public Relations.

5 He may call a meeting of any committee of the Society.

He shall approve all valid bills against the Society after they have been suitably endorsed by the officer, delegate, or chairman or majority of the committee that has incurred the indebtedness specified in the bill, as provided in Chapter VII, Section 1.

He shall sign the certificates of all delegates, and the diplomas of all new fellows if he is satisfied that they have met the requirements of Chapter I.

15 He shall nominate to the Council all members of committees, all delegates to other medical societies, all fellows to fill vacancies among the officers, councilors, censors and commissioners of trial of the Society, unless otherwise provided by the by-laws or by order of the Council.

He shall make appointments to fill vacancies *ad interim* in any of the offices of the Society

He shall be a member *ex officio* of all committees

He shall, in accordance with specific recommendations by the Committee on Ethics and Discipline, either admonish fellows or appoint a board of trial, as provided in Chapter VIII, Section 1

He shall report on the state of the Society at the annual meeting

He shall call one meeting of the Executive Committee between meetings of the Council, and others at his pleasure

In the event of the death or incapacity of the President-Elect, the President, at the annual meeting of the Council, shall nominate members of standing and special committees, unless otherwise provided in the by laws

**Section 2** In the absence of the President, the Vice President shall perform the duties of the President, and in the absence of both, the senior *ex officio* Vice President in point of membership in attendance shall perform the duties of the President.

**Section 3** The President-Elect shall assist the President in the performance of his duties in such manner as the President may direct and in so doing shall be considered to represent the President

At the annual meeting of the Council following the annual meeting at which he was elected, he shall nominate members of standing and special committees, unless otherwise provided for in the by laws

He shall be a member *ex officio* of all committees

**Section 4** The Secretary shall attend all meetings of the Society, the Council and the Executive Committee, and shall record their respective proceedings in separate volumes

He shall cause to be engrossed and shall sign the diplomas of new fellows if satisfied that they have met the requirements of Chapter I, and shall issue all diplomas and certificates of fellowship

He shall notify fellows of votes by the Council or Executive Committee granting permission to retire, to resign, to transfer district membership or to have dues remitted, and of votes depriving them of or reinstating them in the privileges of fellowship

He shall be *ex officio* secretary of all boards of trial, the Board of Supervising Censors, the Committee on Publications and the Committee on Ethics and Discipline, and shall keep the records of each in separate volumes

He shall have custody of the seal of the Society and of all books, papers, manuscripts, prints and paintings belonging to the Society, except such as are in charge of the Treasurer

He shall issue notices of the meetings of the Council He shall issue to every fellow one month before the annual meeting of the Society a program, listing the time and place of that meeting and of the stated meetings of the Council, the boards of censors for that year, and information concerning the payment of assessments and the distribution of publications, if there are any proposed amendments to the by laws he shall provide that each program is accompanied by a copy thereof

He shall transfer fellows from one district to another under the terms of Chapter III, Section 3,

and shall report to the Society at its annual meeting the changes in membership during the year

He shall conduct official correspondence and shall notify officers, delegates and members of committees of their appointments and of their duties

He shall keep a directory of the fellows, and shall publish the same, under the direction of the Committee on Publications, at such intervals as may be determined by the Council He shall furnish this on request to fellows not in arrears

He shall have jurisdiction over the work of the Executive Secretary

He shall perform such other duties as the Society or the Council may require

**Section 5** The Treasurer shall collect and care for all monies due the Society and shall have custody of the treasury records All monies received by any committee, officer or employee on behalf of the Society shall be paid forthwith to the Treasurer

He shall be bonded in such sum and manner as may be directed by the Council, on recommendation of the Committee on Finance

He shall, under the direction of the Council sue for claims due the Society and shall sell, rent or lease any estate belonging to the Society

He shall pay only such bills as have been countersigned by the proper officer or delegate or the chairman or majority of the committee incurring the indebtedness, as provided in Chapter VII, Section 1, and have been approved by the President

He shall render to the Council at its February meeting a full written report of the assets and liabilities on December 31 of the previous year, and also of the financial transactions of the Society during that year

He shall attend the meetings of the Committee on Finance, furnish the committee with such data as it may require and shall make all investments and reinvestments of the Society's funds with authority to buy or sell securities subject to the approval of this committee

He shall arrange for the Cotting luncheons

He shall familiarize the Assistant Treasurer with the fiscal concerns of the Society

He shall perform such other duties as the Society or the Council may require

**Section 6** The Assistant Treasurer shall assist the Treasurer in the performance of such duties as the Treasurer may direct

In event of the death or the incapacity of the Treasurer, the Assistant Treasurer shall assume the duties of the Treasurer until cessation of the incapacity or the next annual meeting of the Council

He shall be bonded in such sum and manner as may be directed by the Council, on recommendation of the Committee on Finance

**Section 7** The Executive Secretary, under the jurisdiction of the Secretary, shall assist the officers, the Council and such committees as may request his services

He shall hold office at the pleasure of the Executive Committee

**Section 8** The traveling and incidental expenses of the officers and committees elected by districts and of standing committees of the Society, on request shall be paid by the Treasurer, on presentation of an itemized bill duly approved by the President

## CHAPTER VII

## COMMITTEES

*Section 1.* Reports of committees containing recommendations that may require prolonged consideration shall be sent in abstract to the Secretary, at least six weeks before their presentation to the Council, for consideration by the Executive Committee and for publication in the official journal.

Every committee, annually on or before December 10, shall forward, to the chairman of the Committee on Finance, an estimate of its expenses for the ensuing fiscal year, which shall show the purpose of any proposed expenditure of \$100 or more and a similar detailed statement of its expenditures for the current fiscal year to and including November 30 with an estimate of expenditures for the current month of December.

All bills \$100 or more incurred by a committee shall be countersigned by a majority of said committee and forwarded to the President for his approval.

All bills less than \$100 incurred by a committee shall be countersigned by the chairman of said committee and forwarded to the President for his approval.

Every committee shall render a written report to the Council at least once a year.

## COMMITTEES ELECTED BY THE DISTRICTS

*Section 2.* The Executive Committee of the Council shall consist of the President, President-Elect, Vice-President, Secretary and Treasurer and a councilor from each district society, chosen as provided in Chapter III, Section 5.

The Executive Committee shall meet at the call of the President. It shall assist the President in preparing matters for consideration by the Council.

It shall act on all questions of retirement, resignation, remission of dues, deprivation of fellowship for arrears, reinstatement following deprivation of fellowship for arrears, and transfer of fellows from one district to another without change of legal residence.

The Executive Committee may appoint and dismiss the Executive Secretary.

It shall authorize or confirm action by the officers in emergency.

The Executive Committee shall perform such other duties as the Council may require.

*Section 3.* The Committee on Public Relations shall consist of the President as chairman and one councilor from each district society, elected as provided in Chapter III, Section 5.

It shall concern itself with the relations between fellows of the Society and the public.

*Section 4.* The Committee on Legislation shall consist of one fellow from each district society, elected as provided in Chapter III, Section 5.

It shall study, initiate and support measures to improve standards of medicine and promote the public welfare. It shall study and oppose such measures as it may deem contrary to the public welfare.

It may employ counsel, subject to approval of the President.

District legislative committees shall be auxiliary to and under the direction of this committee.

*Section 5.* The Committee on Nominations shall consist of one councilor, with another as alternate, from each district society, as provided in Chapter III, Section 5.

It shall nominate the officers and orator of the Society, and shall cause its report to be published in the notice of the annual meeting of the Council.

## STANDING COMMITTEES

*Section 6.* The Committee on Arrangements shall consist of five fellows.

It shall be responsible for all arrangements for the annual meeting of the Society.

The chairman shall furnish the Secretary, on or before April 15, with all the data necessary for the annual program.

The secretary of this committee shall record its proceedings in a volume which shall be filed with the Secretary.

*Section 7.* The Committee on Publications shall consist of five fellows.

It shall supervise the publications of the Society.

It shall publish, when ordered by the Council, a directory of the officers and fellows.

It shall appoint the Shattuck Lecturer in accordance with the provisions of the Shattuck bequest.

It shall inform all readers of papers and discussers of the following rules:

All papers presented at the meetings of the Society shall be the property of the Society. No paper presented in the section meetings at the annual meeting shall occupy more than thirty minutes in its delivery. Each discussion shall be limited to five minutes, unless lengthened by vote of the meeting.

All papers shall be ready for publication, typewritten and accompanied by suitable material for illustrations, if any, when read to the sections or to the Society; and as soon as read they shall be handed to the secretary of the section or of the Society for transmission to the editor of the official journal.

Discussers shall correct and promptly return to the editor for publication, if deemed proper by this committee, the stenographer's transcribed notes of their remarks.

*Section 8.* The Committee on Membership shall consist of five fellows.

It shall consider applicants applying for fellowship according to the provisions of Chapter V, Section 2c.

It shall consider matters relating to honorary or associate fellowship, retirement, resignation, remission of dues, deprivation of fellowship for any cause, reinstatement following deprivation of fellowship for arrears, transfer of fellows from one district society to another, as provided for in Chapter III, Section 3, and shall make recommendations to the Council or the Executive Committee, as provided in Chapter I, Sections 10 and 11.

This committee shall confer with the representatives of the supervising censors as provided in Chapter V, Section 1.

*Section 9.* The Committee on Ethics and Discipline shall consist of five fellows.

It shall investigate and consider, either on charges submitted in writing or on its own initiative, any alleged or apparent offense on the part of any fellow, as provided in Chapter I, Section 9.

It shall either admonish him, request his resignation or report its findings to the President with its recommendations, if as a result of its investigations and after a hearing that has been requested by the fellow, the committee finds that he is guilty of such offense

The President acting on such recommendations shall (a) censure the fellow, or (b) refer the matter to a board of trial, as provided in Chapter VIII, Section 1

A member of the committee shall act as prosecuting officer in cases that come before a board of trial

**Section 10** The Committee on Medical Education shall consist of five fellows

It shall consider matters relating to medical education

It shall annually revise, subject to approval by the Council, the list of recognized medical schools and colleges

**Section 11** The Committee on Public Health shall consist of five fellows

It shall foster the knowledge of the prevention and treatment of disease by any appropriate measures

**Section 12** The Committee on Medical Defense shall consist of five fellows

It may appoint as auxiliary members one fellow in each district

It shall act, under the provisions of the Medical Defense Act, on applications of resident fellows for legal services in the defense of suits for alleged malpractice.

It may take counsel with both plaintiff and defendant in threatened suits

It shall report to the Committee on Ethics and Discipline any instance coming to its knowledge wherein a fellow, in connection with a suit for malpractice, has violated the code of ethics of the Society

**Section 13** The Committee on Society Headquarters shall consist of five fellows

It shall supervise the maintenance of the Society Headquarters

It shall acquire funds for expansion, subject to approval by the Council

**Section 14** The Committee on Finance shall consist of five fellows

It shall recommend to the Council, at the February meeting, the budget for the current fiscal year

The budget shall show in detail the proposed expenditures and their allocation to the various officers, employees, committees, or any other person or persons authorized to expend the same, and shall make available to any fellow on request the purpose of any proposed expenditure of \$100 or more. The budget shall include for purposes of comparison similar items of expenditure for the previous year, if any

It shall consider requests for extraordinary appropriations and shall refer them, with recommendations, to the Council for action

It shall, at the close of the fiscal year after consultation with the Treasurer and with the approval of the Council, determine the amount to be refunded to the several district societies from the unexpended balance on December 31. This amount

shall be apportioned among the district societies according to the number of annual assessments paid to the Treasurer before March 1

**Section 15** The Committee on Hospital Relations shall consist of five fellows

It may appoint as auxiliary members one fellow in each district

It shall concern itself with the relations between the fellows of the Society and hospitals

## CHAPTER VIII

### BOARDS OF TRIAL

**Section 1** A board of trial shall consist of five of the commissioners of trial, appointed by the President, to consider charges against a fellow recommended for trial by the Committee on Ethics and Discipline.

The President shall designate a time and place for the meeting of such board and shall cause due notice thereof to be given to the complainants and to the accused, and to all members of the district society of which the accused is a member

A board of trial may hear fellows who appear in the interest of the accused, but legal counsel shall be excluded

Failure of the accused to appear or be represented at the trial shall be considered *prima facie* evidence of the truth of the charges, and a verdict may be rendered accordingly. In case of conviction, a board shall recommend such sentence as it shall deem best, as provided in Chapter I, Section 10. The Secretary shall enter on the records the proceedings of each board of trial and shall report them to the Society at the next annual meeting for final action

The Secretary shall notify the accused of the findings of a board of trial and of the action of the Society thereon, and he shall notify the several district societies of the sentence imposed

**Section 2** Each commissioner, and each prosecuting officer, shall be paid ten dollars a day for attendance plus his incidental expenses

It shall be a duty of any fellow summoned by the Committee on Ethics and Discipline to appear as a witness before a board of trial. No fellow shall be relieved of this duty without an excuse satisfactory to such a board

## CHAPTER IX

### AMENDMENTS

These by laws may be amended by a majority vote at any annual meeting of the Society, provided the proposed amendment or amendments shall have been submitted previously in writing to the Council, shall have been approved by that body by vote, and shall have been published and forwarded to each fellow, along with the program of the meeting of the Society wherein they are to be considered.

## DEATH

BONNEY — ROBERT BONNEY, M.D., of East Boston, died March 22. He was in his eighty fourth year

A native of Philadelphia, Dr Bonney received his degree from Harvard Medical School in 1898. He was a fellow of the Massachusetts Medical Society and the American Medical Association

He is survived by a brother

## WAR ACTIVITIES

### CIVILIAN DEFENSE

#### FIRST AID FOR AIR-RAID CASUALTIES

First-aid measures applicable to the emergencies of war are embodied in a booklet, *Handbook of First Aid*, issued by the Medical Division of the Office of Civilian Defense in co-operation with the American National Red Cross, for the use of enrolled civilian-defense workers.

The handbook is of pocket size and has twelve chapters titled as follows: "Advice to the Civilian Defense First Aid Workers"; "General Considerations"; "Care of Wounds"; "Dressings and Bandages"; "Hemorrhage"; "Burns"; "Shock (Collapse)"; "Fractures"; "Artificial Respiration"; "Transportation of the Injured"; "Chemical Warfare"; "Miscellaneous Conditions." As indicated by the titles, all material not relevant to the war emergency has been omitted from consideration. The book does not replace the standard Red Cross *Textbook of First Aid*, which is to be used in first-aid classes.

First-aid measures are described within the framework of the plan for emergency medical service: that is, they are described as they will be carried out under war conditions. Numerous illustrations clarify such procedures as the tying of bandages, pressure to stop hemorrhage, the application of traction splints and methods of transporting the injured. Throughout the handbook, the first-aid worker is cautioned against any action that should be left to a physician or any that would handicap the physician when he arrives. One of the cardinal principles emphasized is, Remember you are a first-aid worker and not a physician. For example, the worker is taught not to apply any antiseptic to a wound and not to apply an ointment or a salve to a burn.

About twenty pages are devoted to a discussion of fractures, with detailed descriptions of fixed traction splints for the upper and lower extremities, as well as improvised splints.

The chapter on chemical warfare describes types of war gases and lists briefly under each type the characteristic effects it produces and the appropriate first-aid measures. This chapter also includes instruction on care of burns caused by incendiary bombs containing phosphorus.

The last chapter covers heat stroke, heat exhaustion, heat cramps, frostbite and carbon monoxide poisoning. In connection with the injuries from heat and cold, it is pointed out that an enemy attack can occur at any season and that both victims and defense workers may be exposed to extremes of temperature for many hours.

## CORRESPONDENCE

### POLITICS: A PARALLEL TO MEDICINE

*To the Editor:* When we say that a man is a "good politician" we know what the term implies: that he is intellectually dishonest; that he is more or less a demagogue who plays on the passions of the people; and that he is untrustworthy, promising benefits that he knows are impossible to grant.

We have come to accept this standard set by the politicians as a necessary evil, as something unchangeable and permanent. We do not tolerate it in any other human relation or any other walk of life. Even the business and financial worlds, which are supposed to have low ethical standards, have a code of morals. A Wall Street broker is ostracized if he breaks his promise or his word in a financial transaction. A research worker in medicine who,

to gain a temporary notoriety, intentionally publishes claims known by him to be false is forever outlawed by the profession.

For half a century, we have turned the country over to third-rate and fourth-rate politicians to govern. With a few exceptions, they have chosen politics as a career for reasons other than service to humanity. It is only necessary for a Lincoln to arise to be aware of the gulf between a man of integrity and vision—a man who not only would not lie but could not lie—and the army of men in the municipal, state and federal governments whose regard for telling the truth is mostly theoretical and whose conception of a promise is that it is a temporary expedient and can always be broken after a reasonable length of time. It is strange that politicians do not realize that there is no quality in a man either in public or private life that commands more intense respect and admiration than intellectual honesty. After many years in political life, a politician has compromised his principles so many times that he has ceased to have any principles. Ideals that he once may have had he is apt to view with derision and contempt. He becomes calloused and hard, and speaks the language of the street and gutter.

In the recent mayoralty election in New York City, a prominent politician, in a fifteen-minute radio address, called Mr. LaGuardia a demagogue, a mountebank, a hypocrite, a guttersnipe and a "mucker run amuck." Such freedom of expression seems to be peculiar not only to the vulgar and the low but to politicians as well.

To such men as these,—opportunists, demagogues, grafters and men whose word cannot be trusted,—humanity has entrusted its life, its freedom and its property. By their fruits they are known. The universal woe is a measure of their leadership.

And now a river of blood encircles the earth. And now our young men clean and strong and unbesmirched go forth to die in foreign lands by hideous ways to serve the ends of men called great. These, our sons, so innocent, so gay, shall water the earth with their blood. Guiltless, they are chosen to pay for our folly and greed. They shall lie stabbed and torn and shriveled with fire. Junes will come and go. They will not feel the hot sun or the south wind's warm caress. They will not see the meadows spotted with yellow and gold or the bobolink swaying on slender reed, or breathe the scent of pine and the new cut hay. They are the dead; and all the promise of their youth is blasted in the bud.

So this ignoble breed has set the style for politics in this country. We accept it as a matter of course. It never occurs to us that the style could be changed like women's hats. We have no vision and no conception of the change that would occur if a few thousand high-minded, cultured young people entered political life. If one has ever planted grass seed, one knows that if enough seed is planted only a few weeds will grow. If it is, cultivated carefully, weeds will cease growing entirely.

Until recently, the educated and well-to-do classes of society in this country have had nothing to do with politics. It is a dirty business, and the better elements do not want to soil their hands with it.

A while ago, I read a history of medicine, and I noted a parallel between medicine as practiced one or two hundred years ago and politics, domestic and world politics, as practiced today. If we look on war as a plague and poverty and inequality of opportunity as a disease, we shall appreciate the similarity of the problem and the similarity of the attitude of the public toward it.

A hundred and fifty years ago, the average span of life was twenty years. It is now sixty. The principles of mod-

in medicine were unknown. There was no sanitation. Pestilence and disease were present all the time. Every 10 years or so, Europe was swept with one plague or another: bubonic plague, smallpox, typhus, typhoid fever, and cholera came in their turn. Tuberculosis, diphtheria, and scarlet fever in virulent form were endemic all the time. It is stated that one epidemic of bubonic plague in the Middle Ages removed a third of the population of Europe. In this country, at the beginning of the nineteenth century, an epidemic of yellow fever killed fifty thousand people in Philadelphia.

These plagues were thought to be due to acts of God. To punish the people for their sins. Cotton Mather was a strong exponent of this idea. Religion dominated medicine, and it was considered a blasphemy if anyone questioned the act of God, and made an effort to discover the cause of disease. To dissect a human body for the purpose of learning its anatomy was considered a desecration of the temple of God and was prohibited by law. So there was no chance of learning even the fundamentals of medical science.

People accepted plague, just as we today accept wars, as something inevitable. We hear that man is a fighting animal, and if the impulse to fight is curbed he will degenerate. The Nazis have said that war is a desirable thing and hence they make a virtue of it.

In those days, doctors were, for the most part, ignorant men. The surgeon was a barber, and the physicians came from equally humble walks of life. Moliere, in his plays, gives expression to the contempt of the public for the medical profession. The doctor was a constant butt for ridicule. *The ridicule was justified for he was more or less a humbug, just as the politician is today.* He tried to cover up his ignorance by pomposity and putting on a front. He cultivated a bedside manner, used long words and wrote his prescriptions in Latin. To impress his patients he wore a high hat and frock coat and carried a gold-headed cane. He talked a jargon that would be entirely unintelligible to physicians today. His theories concerning the causes of disease and its treatment were almost entirely wrong. Very little of value has come down to us. For almost every ailment, he prescribed bleeding. A sick person in those days was indeed fortunate if he escaped the clutches of a physician.

A century ago, the causes of diseases were unknown. Every doctor had his private theory. It was usually in conflict with that of his confreres and gave rise to bitter controversies and ill feeling in the profession. Today we see the parallel of this among economists, politicians and planners of one kind or another. There are as many theories of economy today as there were theories of disease in the dark ages of medicine.

Up to a century ago then, man was still living in the Middle Ages, so far as knowledge of the laws that govern disease and health is concerned. He knew no more about the causes of disease than had been known two thousand years before.

Then a miracle occurred. In France, out of the darkness a light shone out. Louis Pasteur had begun his work. For fifty years he carried on his researches to determine the causes of disease in human beings and animals, the blight of the silkworm and the fermentation of wine. He opened up new worlds for science to explore and became the founder of modern medicine. At the beginning he roused tremendous opposition in the medical profession. His every contention was disputed. He was labeled a charlatan and a humbug. Surmounting the greatest abuse ever directed against any scientist, his ideas at last prevailed. A little group in England headed by

Lister adopted his principles. Semmelweis in Austria put them into practice. Oliver Wendell Holmes in the United States listened and introduced his ideas to Boston.

One by one, the plagues that had decimated mankind for hundreds of years were brought under control. Out of the confusion and ignorance that medicine was a hundred years ago,—when superstition quickened and the blind following of tradition were the chief characteristics of the profession,—has grown a mighty system of healing that has spread to all the corners of the earth. Medical science has no secrets, no discovery is patented. It has dedicated itself to the service of mankind. It advances by leaps and bounds. Every week there is a new discovery. It may not be too rash to prophesy that the dream of the ages will be realized that sickness and disease will be banished from the earth. Pasteur's precept still holds in laboratories, hospitals and medical schools the world over. It is very simple—on the hearts and minds of every research worker and medical student is written the command: Seek the truth, follow the truth, tell the truth.

Might not the politicians, might not we all, learn something from the study of the history of medicine? In it, a century ago, one of the greatest revolutions in all history occurred. It was not like an ordinary upheaval conditions reverting to their former state after a period of time. It was a permanent and beneficent revolution, which started an evolutionary process that with ever widening circles has continued to this day. It set new standards, it created a new atmosphere in which reason, truth and knowledge flourished and flowered. It was democratic, it was international—*medical men the world over speak the same language. It sought not to enrich itself, it was governed by no commercial motives, it built no monopoly, it sought only to create a better and healthier world for men and women to live in.*

It is said that wars are inevitable and impossible to eradicate. Must not a mother have said two hundred years ago, sitting by the bed of her dying child, 'It is an act of God, we must suffer for our sins'?

Following the work of Pasteur, thousands of young men of the highest type in all parts of the world began crowding into medical schools and laboratories as volunteers in the new crusade. Today, are our imaginations so feeble that we are unable to visualize the results of thousands and tens of thousands of honorable and intelligent young men and women entering political life, crushing by weight of numbers the forces of greed, dishonesty and hate that now rule the world? If grass seed is sown thickly enough, the weeds will not grow. When that happens, it will be the greatest of all crusades.

Walpole, New Hampshire

## REPORT OF MEETING

### JEWISH MEMORIAL HOSPITAL

At a regular meeting of the Jewish Memorial Hospital in Roxbury on December 3, Dr. Joseph H. Pratt, of the Pratt Diagnostic Hospital, discussed Recent Phases of Pancreatic Disease. He stated that the incidence of carcinoma of the pancreas is not nearly so rare as its clinical recognition indicates. It has been reported that 0.5 to 10 per cent of all autopsies reveal this condition. Engleman in San Francisco, however, reported an incidence of 2.1 per cent of all post mortem examinations and 9 per cent of all cancers found in the series. Its anatomic position

and relations make this organ difficult to palpate even in cases of cancer, but often result in signs and symptoms referable to the biliary tract or duodenum.

From a physiologic standpoint, Dr. Pratt said that the pancreas is an important factor in the digestive functions of the body. Its trypsinogen is converted by the enterokinase of the intestinal tract into the active enzyme, trypsin, which aids in the digestion of protein. In addition, there are diastase for the digestion of starches and lipase for that of fats. Furthermore, a useful alkaline medium, whose presence, incidentally, is often a more significant diagnostic point than that of the ferments, is supplied. The amount of fluid secreted may equal as much as 1500 to 2000 cc. per day, whereas the injection of secretin may call forth as much as 100 to 500 cc. in a single hour. The external pancreatic juices were formerly not considered essential for the maintenance of health and life, and are still ignored in most operations for carcinoma of the pancreas; this belief is now known to be a fallacy. Ligation of the pancreatic ducts results in an elevated blood diastase for several months, and huge doses of pancreatin (5 to 10 gm. daily) are necessary to offset this lack.

The elevation of the blood or urinary diastase has become a valuable test in the diagnosis of acute pancreatitis. This was first noted in 1922, when acute edema without necrosis was originally recognized, but is also present in acute hemorrhagic pancreatitis with fat necrosis. Failures in the use of this test can be attributed to the late application of the test or the late examination of the urine. Even if the disease is progressive, the diastase values return to normal after forty-eight hours at the latest, but they are invariably positive during the first twenty-four hours. The urine is more frequently positive than the blood, but must be examined within two hours of voiding. The importance of making the diagnosis is reflected in the statistics, which reveal a decrease in mortality from 60 or 70 to 25 per cent or less by refraining from operation in acute pancreatitis. The diastase values have been found significantly elevated in no other condition. The test should be carried out daily so that a curve rather than a single determination may be available for the following of a suspected case.

The stools serve as an excellent guide in cases of pancreatic disease and in differentiating jaundice from other causes. In any obstruction of the pancreatic juices, the stools are bulky, light colored and foul smelling. The lack of color persists even in the presence of sufficient bile from the biliary tract. Microscopically, there are fat globules and crystals, as well as muscle fibers, if meat has been ingested. This latter observation is essential in the differential diagnosis of tropical sprue, which is a disturbance in fat digestion only.

In acute edema of the pancreas, the epigastric pain is usually severe, but not agonizing, and can be controlled with morphine in contradistinction to acute hemorrhagic necrosis. The pain may easily be confused with that of acute gall-bladder colic and may be differentiated only by the diastase test. Again, the value of daily determinations is brought out, for if the values return to normal on the second or third day the diagnosis becomes clearer. Such attacks, however, are usually associated with cholecystitis, and the subsequent removal of an affected gall bladder should be carried out, to guard against recurrences and possible acute hemorrhage.

Dr. Pratt described the double-barreled gastroduodenal tube, which has proved so helpful in the study of the pancreatic secretions. It has openings in the stomach portion to allow for decompression of that organ, then

a closed part, then openings in the duodenum that are drained through a separate tube and thus allow separate analysis of stomach and duodenal contents. In the normal person, the intravenous injection of secretin causes a rapid increase of the duodenal contents and a decrease in the amount of bile. Pure pancreatic juice is obtained only in the presence of a normal gall bladder. Normally, there is also a rapid rise in the duodenal alkalinity on the injection of secretin. This test has been employed in an attempt to diagnose carcinoma of the pancreas, in which all the functions of the gland are diminished. In 3 cases in which the stools did not indicate this disease, the secretin test revealed a low volume and a low alkalinity. Acute pancreatitis seems to run normal values in the limited number of cases observed. In cancer, the values for trypsin, lipase and diastase in the duodenal drainage are also low.

In discussing the diagnosis of carcinoma of the pancreas, Dr. Pratt pointed out that painless jaundice is greatly overstressed. Pain is actually a prominent symptom in approximately 60 per cent of cases, and may occur without jaundice. The diagnosis is seldom made without jaundice. In Engleman's series, loss of weight occurred in virtually 100 per cent of the cases, and this has been corroborated at the Pratt Diagnostic Hospital. The amount varies from 10 to 40 pounds. The second most constant finding in both series was that of abdominal pain. This is not characteristic in type, may occur anywhere in the abdomen, and is not necessarily constant. Jaundice is also found in about 60 per cent of cases but is present as a late sign, as shown by the fact that it was of less than six weeks' duration prior to death in over 65 per cent of Engleman's cases. Blood in the stools was found in 75 per cent of those at the Pratt Diagnostic Hospital but in only 13 per cent by Engleman. Dr. Pratt has also observed an elevated blood-sedimentation rate in 75 per cent of his cases, and diabetes in 25 per cent. Also noted was a tendency for the patient to be unduly nervous.

In answer to questions, Dr. Pratt stated that he believes that the sphincter of Oddi is really a sphincter and that the finding of pancreatic ferments in the gall bladder indicates an elevation of pressure. Probably a common channel is the explanation of the association of acute edema of the pancreas with biliary disease. He considers "acute hemorrhagic pancreatitis" a misnomer, the condition being one of intoxication rather than of infection. If such a patient is operated on inadvertently and the condition is recognized,—which should always be easy,—the abdomen should be closed immediately, without exploration or drainage.

## BOOK REVIEW

*The Microbe's Challenge.* By Frederick Eberson; Ph.D. M.D. 4°, cloth, 354 pp., with 1 portrait. Lancaster, Pennsylvania: The Jaques Cattell Press, 1941. \$3.50.

Of all the popular books on bacteriology written in recent years, the reviewer considers this publication outstanding. Soundly and accurately written, in language only technical enough to make the meaning clear, the work covers the entire field of microbes and their relation to illness in man. A glossary, index and suggested readings complete the volume. There are no illustrations, a fact that does not detract from the value of the book. Here is a publication that will appeal to any intelligent layman and should find a place in every public library as a standard reference text.

## REGIONAL ENTERITIS

### Report of Forty Three Cases

RICHARD WARREN, MD \* AND RICHARD H. MILLER, MD †

BOSTON

SINCE 1932, when Crohn, Ginzburg and Oppenheimer<sup>1</sup> awakened widespread interest in regional enteritis, there have been numerous reports of cases in the literature. Few of these have added much to the understanding of the disease. The clinical picture as originally described is still the only aspect of regional enteritis that is well understood. The pathology, diagnosis, prognosis and the most desirable treatment are as yet in completely understood. The etiology is entirely obscure.

From 1930 to 1940, inclusive, 43 cases of regional enteritis were treated at the Massachusetts General Hospital, many of them on the private wards. This article deals chiefly with the results of the treatment of these cases.

#### CLINICAL PICTURE

Crohn and his associates<sup>1</sup> described four stages of regional enteritis: the acute (simulating appendicitis), the diarrheic, the obstructive and the fistulous. In the present series, at the time of admission, 6 cases were acute, 15 were diarrheic, 13 were obstructive, and 4 were fistulous. Five cases were encountered that represented a fifth, or symptomless, stage, most of these were discovered by x-ray at routine gastrointestinal study of symptoms that could not have been caused by regional ileitis. One case, however, was more definite. A pyloroplasty was performed for a proved duodenal ulcer, and at routine exploration of the abdomen a typical regional ileitis was found, both by palpation and by observation. This persisted and was confirmed later by x-ray study, but never caused any symptoms.

The 4 patients who presented themselves with intestinal fistulas had had previous operations. Two additional cases developed fistulas following

operative procedures in this hospital. None of the cases developed fistulas without operation. It is accordingly apparent that the four classic stages of the disease are not necessarily consecutive. The fistulous stage often comes directly after the acute stage, usually following an appendectomy. This fact has been emphasized by Ginzburg.<sup>2</sup>

In the present series, as in those reported by others, regional enteritis was commonest in relatively young people, the average age being thirty, with extremes of fourteen and fifty seven years. Lunich and Crohn<sup>3</sup> have recently reported the oldest case yet recorded, in a patient aged seventy. There is no predilection for race, since only 11 of our cases occurred in Hebrews, and although the ratio of females to males was 29:14, no constant sex predominance has been found in larger series.

In the 33 cases in which data on stools could be obtained, there were only 2 patients whose stools were positive for occult blood or who gave a history of bleeding. This low incidence of intestinal bleeding is in accordance with the experience of others but is surprising in view of the fact that mucosal ulcerations are such a characteristic part of the pathology of the disease.

In our series, the terminal ileum alone was involved in 27 cases, the terminal ileum and the cecum were the site of the lesion in 10 cases, and other areas of small bowel were involved in 6. Ravdin and Johnston,<sup>4</sup> in a survey of the literature, found that the site of the lesion was as follows: terminal ileum alone, 261 cases; terminal ileum and cecum, 100 cases; and other areas of the small bowel, 2 cases. Granulomatous processes in all parts of the gastrointestinal tract have been described. Although several cases of unusual granulomatous inflammatory lesions primary in the stomach or colon have come to our attention, the pathologic findings have not been definite.

\* Assistant in Surgery, Massachusetts General Hospital, and Assistant in Surgery, Harvard Medical School.  
† Fellow for Board of Consultation, Massachusetts General Hospital.

enough to warrant their addition to this series of cases.

Fissure or fistula in ano is a common accompaniment of regional enteritis, and 9 patients had had one or the other at some time in their lives. There is no implication that these lesions are a part of the primary pathologic process. It is rather to be supposed that they are secondary to irritating diarrhea, which so often occurs in ulcerative colitis. No interintestinal or intestinoperineal fistulas were encountered in this series, although such lesions have been described as not uncommon.<sup>1</sup>

### DIAGNOSIS

The diagnosis of regional ileitis is made in one or more of three ways: pathological examination, gross observation at the operating table, and x-ray study. In all the cases in our series, evidence of the disease was demonstrated by at least one of these methods. A diagnosis of regional ileitis was made by x-ray study in 16 of 30 cases that were later proved by operation; no definite x-ray diagnosis was made in 11 cases. In only 3 cases was the disease present when the involved region had appeared normal on x-ray examination. The four x-ray signs of Kantor<sup>8</sup>—the "string" sign, the filling defect in the terminal ileum, the dilated intestine above it, and the conical shape of the barium shadow—were of use in some of the advanced cases, but x-ray study was also helpful in many cases before these signs were evident. The so-called "motility" gastrointestinal series, with the taking of hourly plates to visualize the barium in the terminal ileum, was of the greatest value. We have not used the Miller-Abbott tube, as Boon<sup>9</sup> has done, to make the examination simpler, but this has definite points of merit, the chief of which is the ability to use, thereby, a much smaller amount of barium. We look forward to employing it in the future when the occasion arises. We are of the opinion that, whether or not disease is discovered by the gastrointestinal motility series in the terminal ileum, completeness demands that a barium enema be administered. One patient, who underwent a very radical resection of the right colon and lower ileum, had a prompt subsequent appearance of the disease in the left colon. It was not certain that the disease was absent in this area at the time of the original operation because a barium enema had not been given. A patient with regional ileitis deserves as complete a preoperative study of the intestinal tract as it is possible to give him.

### PATHOLOGY

The typical pathologic picture of regional enteritis is that of a chronic granulomatous process

in the intestinal wall and mesentery. Crohn, Ginzburg and Oppenheimer<sup>1</sup> considered the disease a pathologic entity consisting of chronic inflammation that started in the serosal coat of the intestine and later involved the mucosa in edema, ulcers and pseudopolyps. The mesentery partakes in the edema, so that the mesenteric fat enlarges and apparently creeps up onto the intestinal wall, giving the impression that the intestine has sunk into its mesentery. Many observers, however, have regarded it as a nonspecific process from the pathological viewpoint.<sup>10, 11</sup> The microscopic appearance, which consists in chronic inflammatory elements, fibroplasia, occasional giant cells and even epithelioid cells, could be caused by any bacterial agent or foreign body capable of producing low-grade inflammation, and in this sense, the picture is nonspecific. A considerable degree of uncertainty also envelops certain patients with fistulas in whom secondary infection so destroys the accustomed pathologic appearance that the diagnosis is made rather by the clinical behavior of the disease than by the appearance of the diseased tissue.<sup>2</sup> Hadfield<sup>12</sup> found only 13 of 20 cases of regional enteritis that presented characteristic giant-cell lesions. The histology in the early cases that are discovered at operation for acute appendicitis is also not clear, for few specimens of the intestine are available for study at this stage. In the patients who are seen in this stage and recover spontaneously, it will always be impossible to make an accurate diagnosis. Strongly supporting the belief that the pathologic features of the disease are difficult to define as an entity is the fact that during the last nine years, although hundreds of clinical articles have been written on the subject, pathological journals have been extremely silent concerning the disease. It is probable that further definition of this aspect of regional enteritis will await discovery of the etiologic agent.

### ETIOLOGY

Lengthy discussions of the different theories concerning the etiology of the disease have been published.<sup>4, 7</sup> Although interesting suggestions are made by various authors, no one holds a strong brief for his own theory. Perhaps the most promising hope lies in the search for some agent that primarily obstructs the mesenteric lymphatics. Whether this is a lipoid,<sup>10</sup> some form of silica,<sup>13</sup> or a virus is entirely unknown. The similarity or relation of the disease to lymphogranuloma inguinale, to Johne's disease of cattle,<sup>14, 15</sup> to chronic dysentery,<sup>16</sup> to tuberculosis, to sprue<sup>17</sup> and to Boeck's sarcoidosis is interesting but uninformative.

## TREATMENT

It was at first thought that, since regional enteritis was a specific disease affecting most commonly the terminal ileum, an area so amenable to successful surgical resection, surgery should be

TABLE 1. *Results of Treatment in Cases Reported in the Literature.*

AUTHOR	TYPE OF TREATMENT	TOTAL NO OF CASES	PATIENTS RECOVERED OR IMPROVED	PATIENTS UNIMPROVED	DEATHS IN HOSPITAL
Dixon <sup>18</sup>	Detour operation	14	5	5	4
	Resection	29	24	3	2
Crohn <sup>19</sup>	No operation	11	3	8	
	Operation		36	3	(10-15%)
Mixer <sup>20</sup>	Operation	278		(20%)	(14%)
Kavdin and Johnston <sup>4</sup>	Resection	88	60		
	Detour operation	290	89		
Cutler <sup>14</sup>	Resection	8	2	5	1

the therapeutic method of choice in all cases. It was soon realized, however, that many of the "early" cases either were not regional enteritis or underwent spontaneous regression. Therefore, the form of treatment that has been almost universally advocated has been surgical resection in all

basis for his advocating conservative treatment of all cases; the results from detour operation, or ileocolostomy, are not so good as those from resection; and the operative mortality from resection is about 15 per cent.

Table 2 presents an analysis of the cases at the Massachusetts General Hospital. It reveals the disturbing fact that, although 26 patients had resection\* with only 1 operative death, only 6 of these were symptom free on follow-up inquiry, and only 2 more were not incapacitated by recurrence or persistence of symptoms. Of the 5 patients who had ileocolostomy or detour operations alone, 2 are well, and 3 died later. It is unfair to compare the ileocolostomy group with the resection group because the ileocolostomy often precedes the resection: in other words, if a patient has an ileocolostomy done and continues to have symptoms, but is not too sick for further surgery, a resection is usually performed. The only cases, therefore, that remain for analysis as "ileocolostomies" are those in which the patients got well or those in which they became worse and died. These factors should be taken into account when one considers the poorer results from detour operations as reported in the literature. It has recently been suggested that the reason ileocolostomy

TABLE 2. *Results of Treatment in 43 Cases at the Massachusetts General Hospital*

TYPE OF TREATMENT	TOTAL NO OF CASES	RECOVERY	PERSISTENCE OF SYMPTOMS			DEATHS	
			NO INCA PACI TATION	PARTIAL INCA PACI TATION	TOTAL INCA PACI TATION	IN HOSPITAL	LATER
Resection	26						
First stage	16	2	1	5	6	1	1
Second stage	10	4	1	2	2	0	1

Conservative	12	5	4	1	0	1	1
Totals	43	13	6	8	8	2	6

cases of the disease that were well established, but conservative therapy in the early, acute cases. The results of this policy are not easy to evaluate either in the cases reported in the literature or in those of our series. The length of the follow-up, the criteria for diagnosis, the stage and extent of the disease, and the magnitude of the resection performed are vital data but, unfortunately, are all too scant.

Table 1 gives a summary of the results of treatment in the significant series from the literature. There are four points of interest in this table: Dixon,<sup>18</sup> Crohn<sup>19</sup> and Mixer<sup>20</sup> all report 80 to 90 per cent of good results from resection; Cutler's poor results from resection form a sharp contrast to those of the first three authors, and are the

is unsuccessful in relieving symptoms is that most surgeons do it without transecting the ileum distal to the anastomosis and thus do not ensure complete diversion of the fecal stream from the diseased area. It is certainly logical to suppose that if ileocolostomy alone is to be done, the procedure should be performed in this manner. That this is not a cure-all, however, can be seen from Table 2, which shows that, of the 2 symptom-free patients, 1 had transection performed and 1 did not.

The same difficulty is realized if one compares the patients treated conservatively, in whom the results were excellent, with those treated surgically. The former group comprises, with 1 exception, patients in the acute and less established phase of

\*Two patients had the original resection at other hospitals

the disease. It is obvious that no conclusion can be drawn from conservative versus radical treatment in established regional enteritis unless alternating cases are treated by the two methods. The exception referred to above, however, is instructive. The patient was a thirty-year-old married woman who had suffered from diarrhea and inability to gain weight for six years. Her case was followed for two years. There was definite x-ray evidence of regional inflammation in the terminal 46 cm. of the ileum. This was the one patient in the partially incapacitated group who was conservatively treated. She is able to do all her housework except for occasional periods when she becomes slightly overtired or emotionally upset; the usual diarrhea of two or three stools a day then changes to six or seven a day for a week or so. This occurs approximately every three or four months. A recent x-ray film shows very slight progression of the disease. The patient presents a problem somewhat similar to many who have had unsuccessful reactions.

An attempt was made to analyze the individual cases treated by surgery with a view to finding an indication of why some of the operations were successful and some not. The three important recommendations made by most authors were kept especially in mind: to resect the diseased area, leaving a wide margin of normal intestine between it and the transection; to search for and remove "skip" areas; and to resect widely the involved mesentery and its lymph nodes. Since these 31 patients were operated on by eighteen different surgeons, there was no strict uniformity of operative treatment in this series, and the records of the operative procedures are not informative on the above topics. In 3 of the cases that were unimproved by resection, however, the definite statement is made that the resection was done well beyond the diseased intestine. A specific statement that skip areas were not present was not made, but since in each case the recurrences were in the region of the previous resection, it seems that, even had skip areas been present, they could not have been responsible for the recurrence. It is also confusing that 1 patient, who is now symptom free, presented himself with disease in the ileocecal region and in five skip areas elsewhere in the small intestine. Resection of the ileocecal region and only one of the skip areas was done, leaving four that have caused no trouble.

On the basis of these considerations, it seems that one must agree with Cutler about the low percentage of cures that surgery has to offer. We do not agree with him, however, that, because of this, the medical treatment of the established disease should replace the surgical. It is extremely rare that such patients become spontaneously symp-

tom free as Moschowitz's<sup>21</sup> did. Resection offers a certain percentage—small, perhaps, but nonetheless definite—of cures, and should be advocated when an established case is first recognized as such. By more radical and careful operations and with consideration of the three recommendations of Crohn and Dixon, perhaps our results can be improved. In recurrent cases, it is logical to advocate reoperation only for symptoms that are crippling—namely, uncontrollable infection and obstruction. It is probable that mild or moderate diarrhea alone in these recurrent cases should not be cause for further surgery. Only 1 of 6 cures was the result of a reoperation.

Various specific forms of conservative treatment have been suggested, the chief of which are x-ray therapy and chemotherapy with the sulfonamide group of drugs. One patient, a young boy who died later in tetany, received x-ray treatment without avail when it was first known that his resection had been unsuccessful. We have had no experience with chemotherapy, having been discouraged by the unfavorable report of this form of treatment in one of Rhoads's<sup>22</sup> cases.

#### PROGNOSIS

The prognosis when the disease is not cured by surgery is variable. The patient may fail rapidly, as those with overwhelming secondary infection and fecal fistulas most frequently do (2 patients in our series). There may be remissions, with many years of temporary relief between symptoms (4 cases). The course is most commonly slowly and progressively downward, with gradual weight loss, increase in diarrhea and x-ray evidence of larger areas of intestinal involvement (10 cases). Or the disease may remain, to all intents and purposes, stationary, without evidence of progression (5 cases).

Of the 2 deaths in the hospital, one was from malnutrition in the form of tetany in a young patient who had an acute, severe attack of diarrhea superimposed on a state of chronic, less severe diarrhea of several years' duration. The other patient had tetanic manifestations secondary to failure of calcium and vitamin D absorption; this was associated with failure of absorption of the other fat-soluble vitamins.<sup>23</sup> The deficiencies were controlled in this case by intensive vitamin therapy.

Six patients died following discharge from the hospital after the original operation. As in most diseases, death is the result of a complication rather than of the disease itself. The three complications that are to be feared are extensive infection, malnutrition and intestinal obstruction. Three of the 6 late deaths were from prolonged and extensive infection, which eventually

became uncontrolled. Another case presented vitamin K deficiency as part of the clinical picture. The 2 remaining patients who died after discharge left no clue concerning the cause of death. No patient died from intestinal obstruction per se. The slowly progressive development of obstruction in these cases and the infrequency of gangrene of the intestine result in a type of obstruction that is comparatively simple to deal with.

#### SUMMARY AND CONCLUSIONS

The clinical picture, diagnosis, pathology, etiology, treatment and prognosis of regional enteritis are discussed, and 43 cases are reported.

A fifth, or symptomless, stage of the disease is added to the four accepted stages.

The x-ray examination by the so-called "motility" intestinal series was of great help in diagnosis, being at fault in only 3 of 30 cases.

The pathological picture is not that of a distinct entity.

The various theories concerning the etiology of the disease are mentioned.

The results of surgical resection in established cases in this series were not good, since there were satisfactory results in only 8 out of 26 cases.

Conservative treatment in early cases gave good results.

Since conservative treatment of the established disease, however, gives little hope of cure, radical resection should still be offered these patients as the initial procedure.

The ideal form of treatment of the disease will not be forthcoming until the etiologic agent is discovered.

## COLLES'S FRACTURE\*

WILLIAM DARRACH, M.D.†

NEW YORK CITY

**A** WORKING knowledge of Colles's fracture is essential because the injury is frequent and is often followed by impaired use of the hand and wrist. This fracture is usually caused by a fall on the outstretched hand.

*Anatomy*

The expanded lower end of the radius articulates with the carpal navicular and lunate below and with the ulnar head on the inner side. The head of the ulna is held against the sigmoid cavity of the radius by the pronator quadratus muscle and by the meniscus. The latter is attached to the lower margin of the sigmoid cavity and the base of the ulnar styloid. In addition, the two collateral ligaments are of importance in stabilizing the wrist. The lower radioulnar ligaments are taut only in the extremes of rotation, and the palmar and dorsal radiocarpal ligaments in extremes of flexion and extension.

Lying in close relation to the lower radius are the various tendons passing from the forearm to the wrist and hand. These tendons and the median nerve are liable either to laceration or to adhesions following the hemorrhage and edema that frequently accompany these fractures.

*Pathology*

*Radius.* The plane of fracture of the radius may be horizontal or oblique, single or comminuted. The whole lower extremity is sometimes shattered, with involvement of the lower articular surface. The commonest type of comminution is that of the dorsal surface. The details of the planes of fractures are significant from the standpoint of maintenance of reduction. After the patient has recovered from the anesthetic, the pull of the flexor and extensor muscles crowds the fragments together. If the plane of fracture is single and horizontal, this force aids in holding the fragments in place, but if it is oblique or comminuted the tendency is for the previous deformity to recur in spite of splints. In adolescents, the bone is apt to give way at the epiphyseal plate.

If displacement is present, the lower fragment may be shifted or tilted. In the former event, its axis remains parallel to that of the upper fragment; in the latter, it is angulated. Such displacement may occur in one of four directions: palmar, dorsal, radial or ulnar. Since the bone is

cancellous, there is apt to be some crushing or impaction. Overriding rarely occurs. The most frequent condition found is a combination of dorsal shift and tilt and radial shift and impaction.

*Ulna.* In the majority of cases with displacement, the ulnar styloid is detached near its base because of the pull of the ulnar collateral ligament. Although it usually heals by fibrous rather than by bony union, this lesion is not serious.

*Inferior radioulnar joint.* This joint is intimately associated with pronation and supination, and its derangement may result in persistent pain or limitation of motion. With any shortening of the radius, the articular surfaces lose their proper relations. The meniscus is often torn. Rarely, an actual dislocation at this joint complicates the fracture.

*Adjacent soft parts.* With a backward displacement of an oblique fracture, the sharp jagged edge of the upper fragment can cause considerable damage to the lower fibers of the pronator quadratus muscle, the flexor tendons and even the median nerve. Rarely, the ulnar nerve may be injured. Injury to the short thumb extensors may result in subsequent rupture.

*Associated injuries.* Fracture of the navicular and luxation of the lunate are sometimes associated injuries.

*Symptoms and Signs*

The symptoms of the break are pain, which may be very mild at first, and weakness of the hand and wrist. Localized tenderness over the line of fracture can be elicited both directly and indirectly. If the patient is seen within a few minutes of injury, a narrow, sharply elevated transverse swelling will be noted on the dorsal surface at the site of fracture, because of hemorrhage. As the blood extravasates and edema ensues, the swelling extends and becomes less prominent. With the usual dorsal and radial shift of the lower fragment, the typical silver-fork deformity occurs. The normally flat dorsal surface of the lower forearm, wrist and hand then shows a distinct elevation. At the same time, the palmar concavity disappears. With any shortening of the radius, the relation of the two styloids is altered. Instead of being almost a centimeter lower, the radial styloid will be nearer the level of the ulnar. Normally, a line passing down the middle of the forearm follows the middle metacarpal and the middle finger. With a radial shift of the lower

\*Presented before the New England Postgraduate Assembly, Cambridge, Massachusetts, October 30, 1941.

†Professor of clinical surgery, Columbia University College of Physicians and Surgeons, attending surgeon, Fracture Service, Presbyterian Hospital.

fragment, this line tends to follow the fourth metacarpal and ring finger. At the same time, the ulnar head becomes more prominent.

### Examination

Examination should be made as gently as possible. With the story of a fall followed by pain and impairment of function, one should presume that a fracture exists until one can prove the contrary. Localized tenderness increases the probability. Actual deformity confirms the diagnosis of fracture with displacement. After a test for possible nerve injury, the examination is completed by x-ray films taken in two planes. In studying x-ray films, it is not enough to establish the primary diagnosis; other bone lesions should be looked for. The main problem, however, is to decide how the planes of fracture run and what displacement exists. Such evidence is needed to decide what maneuvers are necessary to reduce the displacement, what is required to maintain the reduction, how long immobilization is necessary and, lastly, what the probable outcome will be.

### Treatment

**Reduction.** Any displacement of fragments should be corrected except under certain conditions. This requires an anesthetic, either local or general, not only to lessen pain but to reduce the amount of secondary trauma. All materials for immobilization should be assembled before the anesthetic is given. The essential principle in reduction of displacements is to disengage the fragments before trying to manipulate the lower one into place. This is accomplished by traction on the hand, countertraction being applied to the upper arm by an assistant or broad band fastened to the end of the table and the elbow being flexed to a right angle. Traction should be slow and gentle at first and gradually increased as necessary, aided perhaps by rocking of the lower fragment. After the fragments have been disengaged, the lower one can be swung and pushed into place. The exact maneuvers necessary should be planned according to the x-ray evidence. After reduction, the position should be checked under the fluoroscope.

**Immobilization.** The type of splint varies with the habits and desires of the surgeon. Some form of molded plaster splint is perhaps the favorite. I prefer the so-called "sugar-tong" splint, a single strip of plaster that starts in the palm opposite the metacarpal necks, passes up the palmar aspect of the forearm around the flexed elbow and down the dorsal aspect to the metacarpal heads. It is essential to allow free motion at the metacarpophalangeal and interphalangeal joints. As soon as the plaster has set and a bandage has been applied,

post-reduction films should be taken, not only for the surgeon's information but also for his protection. After the swelling has subsided for seven to ten days, it may be wise to change to a circular plaster gauntlet from the midpalm to the upper forearm.

Too early removal of splints tends to prolong rather than shorten convalescence. If the splints allow free motion at the metacarpophalangeal and interphalangeal joints and the patient is made to keep his fingers moving, this not only will maintain range and power in these joints but by internal massage will help the circulation at the site of fracture and thus hasten union.

**Treatment of different types.** From the standpoint of treatment and prognosis, fractures of the lower radius can be divided into four main groups, with three minor types.

**Fractures without displacement**, of course, require no reduction and no anesthetic. After three or four weeks, the splints may be replaced by a leather wristlet. In such fractures, the patient should have complete return of function.

When *fractures with a single horizontal plane of fracture and slight or no impaction* are seen early, complete reduction should be possible. The muscle pull tends to hold the fragments in place, and the wrist can be put in a comfortable mid-position. The period of immobilization needed is but little longer than that in the first group.

When *the plane of fracture is oblique* or when *there is comminution of the dorsal surface*, there is a strong tendency, because of the muscle pull, for the dorsal shift and tilt to recur. This can be partially overcome if the splint is applied with the wrist in strong flexion and moderate adduction. The position can be changed to a more comfortable one during the third week, but splints should be retained for five or six weeks.

There is a group of cases, perhaps 5 per cent, in which *the comminution is so extensive that no form of splint alone prevents collapse and shortening*. In this type, it is well worth while to use the double Kirschner wire and plaster method. One wire is passed through the second, third and fourth metacarpals near their base (the fifth is usually missed). A second wire is inserted higher in the forearm. At first, I used this wire through the radius a little above the middle, but experience has shown that it is better to place it in the upper ulna just distal to the coronoid. After the wires are in place and yoked, reduction is obtained by traction on the wires, with necessary molding. While this is held, a circular plaster is applied, incorporating the two wires. These are left in place for five to seven weeks.

In *very old patients*, it is often wiser to provide protection for a short period without reduction, active motion being started as soon as possible.

Occasionally, *loose fragments* of bone are displaced so as to lie amid the tendons either in front or behind. These should be removed as soon as union has become fairly firm.

Three types of *late disability* can be helped by operative treatment: in cases with persistent posterior shifting of the lower fragment, in which the flexor tendons rub against the sharp edge of the upper fragment, with marked interference with the handgrip, simple removal of the projection through a lateral approach restores the power;

when there is derangement of the lower radio-ulnar joint from shortening of the radius, which interferes with rotation, the pain, disability and deformity of the prominent ulnar head can be relieved by a subperiosteal resection of the lower 2 cm. of the ulna; and in cases with marked dorsal tilt and shift requiring an osteotomy, as the lower fragment is swung forward into position, a triangular space is left that can be filled with the new callus from the dorsal surface—if the ulnar head needs resection, this bone can also be used to fill the vacancy.

## THE PHARMACODYNAMICS OF SULFADIAZINE IN MAN\*

HERMAN D. RATISH, B.S.,† NATHAN H. SHACKMAN, M.D.,‡ AND JESSE G. M. BULLOWA, M.D.§

NEW YORK CITY

**S**ULFADIAZINE, an analogue of sulfapyridine, (2-sulfanilamido-pyrimidine) has recently been synthesized by Roblin and his associates.<sup>1</sup> Reports on its fate, mode of action, absorption and toxicity in animals<sup>2,3</sup> and in man<sup>4-7</sup> have appeared. The present discussion deals with observations on its pharmacodynamics in man.

### MATERIALS AND METHODS

Ninety-eight men with upper respiratory infections or convalescing from pneumonia were studied. The drug¶ was given orally, intravenously, subcutaneously, intramuscularly and rectally. Observations were made on the fate of single oral doses of 2, 3, and 5 gm. and with repeated doses of 1 gm. every four and every six hours. Intravenously, 5 gm. of sodium sulfadiazine dissolved in 50 cc. of sterile distilled water was injected within one to three minutes. Infusions of 500 or 1000 cc. of a 0.5 or 1.0 per cent solution of sodium sulfadiazine in sterile physiologic saline were given at the rate of 2.5 to 3.0 cc. per minute. Subcutaneously, 1000 cc. of a 0.5 per cent solution of sodium sulfadiazine in saline was administered over a period of two hours. Intramuscularly, 2 or 3 gm. of sodium sulfadiazine in 50 cc. of sterile distilled water was injected into the upper outer quadrant of the buttocks. Rectally, 5 gm. of sulfa-

diazine was given as a retention enema (starch). Determinations of free and total sulfadiazine in the blood were made at intervals of fifteen minutes for the first hour, at hourly intervals for the next five hours and at intervals of twenty-four hours until the blood showed negligible amounts. Collection and analysis of urine were continued until only traces were detected. The distribution of the drug was studied in the spinal, pleural and peritoneal fluids. The concentrations were determined by the method of Bratton and Marshall<sup>8</sup> by means of a photoelectric colorimeter.

### ABSORPTION FROM GASTROINTESTINAL TRACT

#### Oral Administration

The sulfadiazine concentrations in the blood obtained after single oral doses of 2, 3 and 5 gm. are shown in Figure 1. At the end of four hours, single 2-gm. doses of sulfadiazine in 5 subjects resulted in blood levels of the free drug ranging from 2.0 to 3.5 mg. per 100 cc. Single 3-gm. doses given to 6 subjects yielded blood levels varying from 2.5 to 4.0 mg. per 100 cc. Seven subjects who received 5-gm. doses had concentrations of free sulfadiazine ranging from 3.6 to 5.5 mg. per 100 cc. In all cases, measurable quantities of the drug were found in the blood for seventy-two hours.

Multiple oral doses of sulfadiazine were administered to 40 subjects to determine and evaluate the blood concentrations obtainable with different dosage schedules. When statim doses of 2, 3, 4 and 5 gm. were followed by 1 gm. every four or six hours, day and night, it was found that those subjects who had received 4 or 5 gm. as an initial dose maintained slightly higher levels

‡Chemist, Littauer Pneumonia Research Fund.

§Littauer Fellow in Pneumonia Research, Harlem Hospital.

¶Clinical professor of medicine, New York University College of Medicine; visiting physician, Harlem Hospital; visiting physician, Willard Parker Hospital.

¶We are indebted to Dr. W. G. Malcolm, of Lederle Laboratories, Incorporated, Pearl River, New York, for generous supplies of sulfadiazine and sodium sulfadiazine.

than those who had received the smaller doses. The levels, however, were maintained as well when the continued doses were given at intervals of four or six hours.

### Rectal Administration

Following a retention enema containing 5 gm of sulfadiazine, the concentration in the blood

FIGURE 1 Sulfadiazine (Free and Total) Blood Concentrations and Urinary Excretions after Single Oral Doses of 2 (A), 3 (B) and 5 (C) Gm of Sulfadiazine

was never above 10 mg. per 100 cc, but traces were detectable for seventy two hours

### PARENTERAL ADMINISTRATION

Parenteral administration may be advisable because some patients cannot take the drug orally or an early high concentration is required. The available routes are intravenous, subcutaneous and intramuscular.

### Intravenous Route

High concentrations were found immediately in all subjects receiving sodium sulfadiazine intravenously. Free sulfadiazine in the blood reached concentration peaks varying from 16 to 24 mg per 100 cc in ten to thirty minutes after injection of 5 gm of the drug. The blood concentrations

decreased gradually for the first six hours. This was followed by a more rapid decline for the next eighteen hours, and traces were detectable after forty eight hours.

Because of the rapid drop in concentration following intravenous injection of the drug, an attempt was made to maintain high levels with a continuous slow infusion. A series of 8 subjects received infusions of 500 to 1000 cc of a 0.5 or 1.0 per cent solution of sodium sulfadiazine at the rate of 2.5 to 3.0 cc per minute. During the infusion, a steady increase in concentration occurred. Peaks ranged from 11.9 to 19.2 mg of free sulfadiazine per 100 cc. The decline in concentration following the cessation of the infusion, although steep, was not so sharp as that following a rapid injection of the same amount of drug in greater

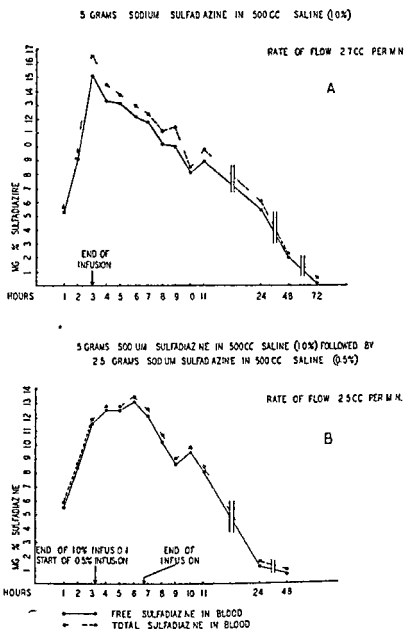

FIGURE 2 Sulfadiazine (Free and Total) Blood Concentrations (A and B), after Continuous Intravenous Infusion of Sodium Sulfadiazine, Using Solutions of Different Strengths

concentrations. Figure 2 shows representative curves.

In 1 subject, an initial infusion of 5 gm of the sodium salt of the drug in 500 cc. of physiologic saline solution produced a blood concentration of

zine. Gross hematuria occurred on three occasions. In no case did albumin or casts appear in the urine as a result of the drug. Neither intramuscular nor subcutaneous injections produced

ment of the concentration of the infusion liquid or by regulation of the rate of flow. Although the immediate levels obtained with the slow infusion method are somewhat lower than those

any adverse local or general reactions. The high pH (9.5) of the solutions was apparently without harmful effects.

### DISCUSSION

Sulfadiazine is readily absorbed from the gastrointestinal tract. Blood concentrations obtained are generally higher than those observed with similar doses of sulfapyridine and sulfathiazole. The drug disappears from the blood more slowly than either of these. The amount conjugated in the blood is less than that with sulfapyridine or sulfathiazole. The conjugated fraction in blood and urine does not increase with continued administration. In the urine, about a third is found to be conjugated, although in exceptional cases a much larger proportion may be excreted in this form. Rapid urinary excretion of the drug may account for the small quantities of conjugated sulfadiazine in the blood.

When both rapid attainment and maintenance of high blood levels are desirable and oral administration is not feasible, the intravenous infusion of sodium sulfadiazine is practical. Blood concentration may be varied either by adjust-

tained with the rapid intravenous injection of similar dose, a high concentration is more readily maintained. This method is safe, flexible and efficacious.

Sulfadiazine is widely and readily distributed in body fluids. It penetrates well into the pleural and peritoneal cavities. Concentrations in the spinal fluid are usually about two thirds those of the simultaneous blood levels.

With initial doses of 2, 3, 4 and 5 gm. followed by 1 gm. every six hours, levels are obtained that are similar to those reached when the drug is given every four hours. Blood concentrations are independent of the total dose and the dose per kilogram of body weight.

The incidence of toxic reactions is less with sulfadiazine than with sulfapyridine and sulfathiazole. When reactions occur, they are mild.

### CONCLUSIONS

Sulfadiazine is readily absorbed from the gastrointestinal tract.

High levels may be obtained by several routes but a rapid attainment and maintenance of high

than those who had received the smaller doses. The levels, however, were maintained as well when the continued doses were given at intervals of four or six hours.

### Rectal Administration

Following a retention enema containing 5 gm of sulfadiazine, the concentration in the blood

decreased gradually for the first six hours. This was followed by a more rapid decline for the next eighteen hours, and traces were detectable after forty eight hours.

Because of the rapid drop in concentration following intravenous injection of the drug, an attempt was made to maintain high levels with a continuous slow infusion. A series of 8 subjects received infusions of 500 to 1000 cc of a 0.5 or 1.0 per cent solution of sodium sulfadiazine at the rate of 25 to 30 cc per minute. During the infusion, a steady increase in concentration occurred. Peaks ranged from 11.9 to 19.2 mg of free sulfadiazine per 100 cc. The decline in concentration following the cessation of the infusion, although steep, was not so sharp as that following a rapid injection of the same amount of drug in greater

FIGURE 1 Sulfadiazine (Free and Total) Blood Concentrations and Urinary Excretions after Single Oral Doses of 2 (A), 3 (B) and 5 (C) Gm of Sulfadiazine

was never above 10 mg per 100 cc, but traces were detectable for seventy two hours.

### PARENTERAL ADMINISTRATION

Parenteral administration may be advisable because some patients cannot take the drug orally or an early high concentration is required. The available routes are intravenous, subcutaneous and intramuscular.

### Intravenous Route

High concentrations were found immediately in all subjects receiving sodium sulfadiazine intravenously. Free sulfadiazine in the blood reached concentration peaks varying from 16 to 24 mg per 100 cc in ten to thirty minutes after injection of 5 gm of the drug. The blood concentrations

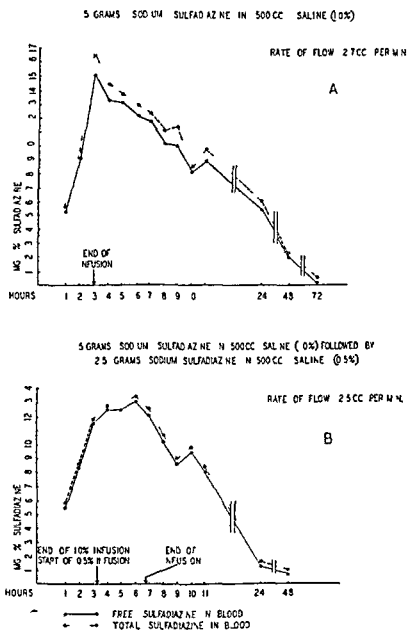

FIGURE 2 Sulfadiazine (Free and Total) Blood Concentrations (A and B) after Continuous Intravenous Infusion of Sodium Sulfadiazine, Using Solutions of Different Strengths

concentrations. Figure 2 shows representative curves.

In 1 subject, an initial infusion of 5 gm of the sodium salt of the drug in 500 cc of physiologic saline solution produced a blood concentration of

11.5 mg. per 100 cc. at the termination of the infusion (Fig. 2B). When this was immediately followed by 500 cc. of a 0.5 per cent solution at the same rate of flow, blood levels between 12 and 13 mg. per 100 cc. were maintained for the duration of the infusion (four hours). In another case, the initial infusion of 5 gm. sodium sulfadiazine in 1000 cc. of saline solution was followed by oral doses of 0.5 gm. every four hours. Concentrations between 9 and 11 mg. per 100 cc. were maintained.

### Subcutaneous Route

Three subjects received 5 gm. of sodium sulfadiazine subcutaneously in 1000 cc. of physiologic saline solution; the hypodermoclysis required two hours. The highest concentration of the free sulfadiazine was reached in six hours, the peaks being 7.5, 7.8 and 8.2 mg. per 100 cc. respectively (Figure 3). The increase, as well as the drop, in

FIGURE 3. *Sulfadiazine (Free and Total) Blood Concentrations Following Hypodermoclysis of 5 Gm. of Sodium Sulfadiazine in 1000 Cc. Saline Solution in 3 Patients.*

concentration was gradual, and in one subject a concentration of 1.0 mg. per 100 cc. was detectable at the end of one hundred and twenty hours.

### Intramuscular Route

Two subjects were given 2 and 3 gm. of sodium sulfadiazine (in 50 cc. of sterile distilled water) intramuscularly in one minute. The pH of the solution was 9.5. The blood levels reached peaks of 6.2 and 8.5 mg. of free sulfadiazine per 100 cc., respectively, in one hour and dropped gradually (Fig. 4). The blood-level curves show a similarity to those obtained after intravenous injection.

### CONJUGATION IN BLOOD

Conjugated sulfadiazine is present in small amounts in the blood. Different subjects showed only moderate variations in the quantity of conjugated sulfadiazine, and the quantities were small irrespective of the amount administered or its portal.

In 1 case, the conjugated sulfadiazine in the blood was markedly elevated. This patient was given a single dose of 5 gm. of sulfadiazine orally. Concentrations of the free and conjugated drug

FIGURE 4. *Sulfadiazine (Free and Total) Blood Concentrations Resulting from Intramuscular Injections of 2 (A) and 3 (B) Gm. of Sodium Sulfadiazine in Distilled Water.*

were detectable seven days after it had been administered. At the end of ninety-six hours, the blood contained 5.3 mg. of the conjugated form per 100 cc. and 2.3 mg. of the free form. The urine in this case also showed an unusual output of conjugated sulfadiazine. The total recovery was 61.8 per cent, two thirds of which was conjugated. This subject had nephrosclerosis with azotemia (a blood creatinine of 6.0 and a blood urea nitrogen of 130 mg. per 100 cc.).

### ELIMINATION

Discontinuance of administration is followed by early rapid excretion, which subsequently becomes slower. Sulfadiazine was observed in the urine within thirty minutes after oral administration, and immediately after intravenous injection. Within seventy-two hours, most of it had been eliminated. Approximately 50 per cent of the total amount recovered was excreted in the first twenty-four hours, and about 80 per cent in forty-eight hours. For as long as six days, both free and conjugated forms could be detected in measurable quantities in the urine.

The amount of sulfadiazine (free and conjugated) recovered from the urine varied from 30.4 to 94.5 per cent of the dose given, with an average of 60.5 per cent (Table 1). After oral administration, the recovery averaged 56.1 per cent, and after intravenous, intramuscular and subcutaneous administration, the average recovery was 69.7 per cent.

Generally, there was a lag of twenty-four hours in the appearance in the urine of the conjugated as compared with the free form. In most cases,

of the total amount recovered in the urine, about 35 per cent was excreted as conjugated sulfadiazine, with extremes of 11.4 and 71.4 per cent. Of the total amount of conjugated drug recovered, approximately 45 per cent was accounted for in the first twenty-four hours, and 75 per cent in the first forty-eight hours. The percentage of conjugated sulfadiazine excreted from day to day was

free drug was 21.3 mg. per 100 cc., as compared with 15.2 mg. in the blood.

#### DISTRIBUTION BETWEEN CELLS AND PLASMA

Several blood samples, at hourly intervals, were drawn from each of 6 subjects to study the distribution of the drug in blood cells and plasma. Approximately 80 per cent of the sulfadiazine was

approximately the same in all patients, irrespective of the duration of administration (Fig. 1). It appears that the rate of conjugation, as measured by urinary excretion, is a characteristic of the patient and does not depend on the amount of drug given or its route of administration.

#### DISTRIBUTION IN BODY FLUIDS

The drug may be detected in high concentrations in the spinal, pleural and peritoneal fluids. As indicated in Table 2, the spinal-fluid levels of free sulfadiazine varied from 56 to 95 per cent of the simultaneous blood levels. In some cases (M. L., R. L. and J. W.), a tendency to maintain a fairly constant relation to the blood levels was observed. In pleural fluid, collected without local anesthesia, the range was 54 to 132 per cent of the blood levels. In none of these, had the drug been injected into the pleural space. The possibility that the excretion of the drug from the pleural fluid into the blood is slower than its absorption from the blood is a probable explanation for the high pleural-fluid concentrations. In one subject (A. P.), following an intravenous injection of 5 gm. of sodium sulfadiazine, a concentration of 8 mg. of the free drug per 100 cc. was observed in the ascitic fluid in ten minutes. At the end of forty minutes, the concentration of the

found in the plasma. There was no relation between the distribution and blood levels. The amounts of conjugated sulfadiazine were small in both cells and plasma.

#### SOLUBILITY

Sulfadiazine was found to vary in solubility with the medium employed. When the solubility of the drug was tested at 22°C. and at 37°C., it was found to be 9 and 12 mg. per 100 cc., respectively, in water, 13 and 19 mg. per 100 cc. in physiologic saline solution, and 136 and 204 mg. per 100 cc. in whole blood. In serum, at 22°C., it was soluble to the extent of 206 mg. per 100 cc.

#### TOXICITY

In the subjects reported herein and in a larger series (over 300 cases) to be reported, the incidence of toxic manifestations was relatively low. Nausea and vomiting occurred in 10 per cent of the cases. A morbilliform rash was seen in 3 patients, 1 of whom also had a moderately severe conjunctivitis. Blood changes and mental disturbances were not encountered. Crystals in the urine were less frequently observed than with the other drugs. In 1 case, at operation, crystals of sulfadiazine were present in the pleural fluid following an intrapleural injection of a solution of sodium sulfadiazine.

zine. Gross hematuria occurred on three occasions. In no case did albumin or casts appear in the urine as a result of the drug. Neither intramuscular nor subcutaneous injections produced

ment of the concentration of the infusion liquid or by regulation of the rate of flow. Although the immediate levels obtained with the slow infusion method are somewhat lower than those ob

any adverse local or general reactions. The high pH (9.5) of the solutions was apparently without harmful effects.

DISCUSSION

Sulfadiazine is readily absorbed from the gastrointestinal tract. Blood concentrations obtained are generally higher than those observed with similar doses of sulfapyridine and sulfathiazole. The drug disappears from the blood more slowly than either of these. The amount conjugated in the blood is less than that with sulfapyridine or sulfathiazole. The conjugated fraction in blood and urine does not increase with continued administration. In the urine, about a third is found to be conjugated, although in exceptional cases a much larger proportion may be excreted in this form. Rapid urinary excretion of the drug may account for the small quantities of conjugated sulfadiazine in the blood.

When both rapid attainment and maintenance of high blood levels are desirable and oral administration is not feasible, the intravenous infusion of sodium sulfadiazine is practical. Blood concentration may be varied either by adjust-

tained with the rapid intravenous injection of a similar dose, a high concentration is more readily maintained. This method is safe, flexible and efficacious.

Sulfadiazine is widely and readily distributed in body fluids. It penetrates well into the pleural and peritoneal cavities. Concentrations in the spinal fluid are usually about two thirds those of the simultaneous blood levels.

With initial doses of 2, 3, 4 and 5 gm. followed by 1 gm. every six hours, levels are obtained that are similar to those reached when the drug is given every four hours. Blood concentrations are independent of the total dose and the dose per kilogram of body weight.

The incidence of toxic reactions is less with sulfadiazine than with sulfapyridine and sulfathiazole. When reactions occur, they are mild.

CONCLUSIONS.

Sulfadiazine is readily absorbed from the gastrointestinal tract.

High levels may be obtained by several routes but a rapid attainment and maintenance of high

blood levels is best accomplished with continuous slow infusion.

The amount of conjugated sulfadiazine in the blood is small, usually less than 20 per cent

Although the amount of conjugated sulfadiazine excreted in the urine varies in different subjects, approximately 35 per cent is excreted in this form

The drug diffuses well into the body fluids

The ratio of spinal-fluid to blood concentration appears to be constant.

Toxic manifestations of sulfadiazine are less frequent and milder than those noted with sulfapyridine and sulfathiazole.

## UNUNITED HIP FRACTURES\*

OTTO J HERMANN, MD†

BOSTON

DURING the last decade or so, surgeons have concentrated on the initial reduction, fixation and aftercare of fresh fractures of the femoral neck. As a result, the percentage of good end results typified by solid union and painless functioning has markedly increased. However, as I<sup>1</sup> contended in 1940, when I had occasion to discuss the problem of ununited hip fractures, ununited femoral neck fractures, including many of the nonfunctioning, painful types, still occur. To render the limb painless and functioning, some type of reconstructive (or as the late Dr F J Cotton tersely put it, "destructive") type of operation is required.

### METHODS

Various types of reconstructive procedures for these cases of nonunion have evolved. But I still believe that the following five methods form a good armamentarium for the surgeon attempting to do such work: the Colonna<sup>2</sup> (a modification of the Whitman<sup>3</sup>); the Magnuson<sup>4</sup> (a modification of the Brackett<sup>5</sup>), the various bone stimulating operations—direct grafting, chip grafts, peg grafts and hole drilling, the fusion operation, and the simple oblique McMurray<sup>6</sup> osteotomy method. Since my views on the first four methods have not changed radically during the last two years, I quote below what I had to say of them at that time.

The fifth, the McMurray method, I practically passed over because up to that time my experience with it had been short and unsatisfactory. Since

then, I have done such osteotomies in 8 cases, with gratifying end results in 6. The remaining 2 patients were treated too recently for the ultimate outcome to be judged, all that I can say about them is that to date they are progressing well. My experience with the method during the last two years has impressed me very favorably with its simplicity, its wide adaptability and its promise of a high rate of good end results and of a return to normalcy.

To offer a basis of comparison between methods, I shall review the operative procedure of the first four methods and my evaluation of them, as I gave them in the previous paper, with some very minor revisions. Following this, I shall consider the McMurray oblique osteotomy.

The Colonna type of reconstruction consists in: sectioning close to their insertions of all muscles attached to the region of the greater trochanter, with preservation of a thin layer of fibromuscular tissue over the upper end of the bone; removal of the head; placing of the upper extremity of the femur deeply and firmly within the acetabulum, transplantation of the gluteus medius and minimus group of muscles downward on the shaft of the femur as far as they will reach, and the secure fastening of them to the bone; after wound repair and dressing, application of a plaster-of-Paris spica with the leg in 20 to 30° abduction; at the end of four weeks, cutting away of the lower posterior half of the cast in the affected leg so as to allow knee flexion several times a day; removal of the entire cast in the sixth week, placing of the leg in a special type of foot sling hitched to a Balkan frame, and institution of a special series

\*Read by title at the annual meeting of the New England Surgical Society, Hanover, New Hampshire, September 5, 1941.

†Assistant professor of surgery, Tufts College Medical School, associate in surgery, Harvard Medical School, surgeon-in-chief, Bone and Joint Service, Boston City Hospital.

of exercises; and use of crutches at the eighth week and direct weight bearing one to two weeks, or more, later, depending on the individual case.

The essentials of the Magnuson<sup>4</sup> method (a modification of the Brackett method) are: exposure by the Smith-Petersen or the Callahan approach; removal of fibrous tissues between the fractured ends, followed by a test to ascertain whether the head is viable or nonviable; hollowing of the head in the form of a cone, pointing upward and slightly backward; rotation of the femur inward and, with a thin-bladed chisel, removal of the trochanter in a line sloping from the base of the neck of the shaft; rounding of the end of the shaft in the same curve as that in which the head has been hollowed out; abduction of the leg so that the upper end of the shaft may be pried into the head; reattachment of the trochanter to the shaft on the cut surface so that it is moved downward and outward and held in that position by heavy silk ligatures; application of a plaster-of-Paris spica, which is retained for eight to twelve weeks, occasionally longer in my experience (that is, until bony union has taken place); removal of the spica, the legs being kept in some abduction, however; finally, periodic clinical examinations and check-up roentgenograms to determine when actual direct weight bearing can be started.

The various direct bone-grafting, pegging and hole-drilling methods, I believe, need not be described, since they are so varied. Suffice it to say that when I decide to use such a procedure I combine several. These operations are followed by plaster-of-Paris spica fixation for ten to fourteen weeks, or until union has been established, and then by the use of crutches and protective ambulatory splints until definite firm union has been obtained.

The hip-fusion method is generally performed by means of Hibbs's procedure, or with some modification, when the head of the femur must be removed or is useless. In these cases, Cotton<sup>7</sup> combined Hibbs's fusion operation with Albee's old plan of squaring. Following the operation, a plaster-of-Paris spica is applied and retained until fusion is established. As a rule, this takes twelve to sixteen weeks. A walking spica is then applied, or if fusion is firm, a protective ambulatory splint and crutches or crutches alone are used. No direct weight bearing is permitted until union has been firmly established clinically and roentgenographically.

Dr. Charles H. Bradford,<sup>8</sup> who is with the American Hospital in England, describes a hip-fusion method that is being worked out by Dr.

Britten, who does the equivalent of a McMurray osteotomy, slides the shaft inward and lays a wide solid piece of tibial graft above it like a roof, firmly set in the chiseled groove in the ischium just below the acetabulum. Dr. Bradford considers this type of arthrodesis to be a revolutionary development that may replace all other forms of hip fusion. I mention it because I consider it much simpler and basically sounder than the prevalent hip-fusion methods.

The McMurray<sup>6</sup> osteotomy is a bifurcation operation based on the suggestion of Lorenz<sup>9</sup> in which the shaft of the femur is transferred directly under the lower margin of the acetabulum and head of the femur. The chief purpose of this operation is to change a shearing force into a direct one. The following are the steps in the procedure: a 15-cm. incision is made along the lateral side of the upper end of the femur in the trochanteric area; the fracture site is exposed so as to place the osteotomy line accurately; an oblique osteotomy is performed, beginning on the outer side of the shaft, generally about the lower end of the greater trochanter, and ending above the tip of the lesser trochanter; the upper end of the shaft of the femur is pried and shoved inward until the cut end is under the acetabulum and femoral head—this is followed by repair of the wound; a plaster-of-Paris fixation is used for a period long enough to ensure union at the site of the osteotomy (varying in my cases from eight to fourteen weeks). This fixation of the limb is in the neutral position in very slight abduction, to prevent the development of knock-knee following removal of the plaster cast. McMurray asserts the objection that this protracted fixation by plaster spica is likely to be followed by troublesome rigidity, especially if the knee joint does not hold, since in that event there is no torsion of the limb and consequently no continued strain on the joint, which lies comfortably in neutral, slight flexion position.

McMurray warns that the osteotomy should not be carried out on too high a level because the shaft of the femur cannot then be put under the head and acetabulum. Also, if the osteotomy is done at too low a level, no weight is borne directly through the shaft of the femur, so that the strain at the site of nonunion remains unaltered. The obliquity of the osteotomy makes more certain that union occurs between the fragments. McMurray further stresses the value of the correct position of the transferred shaft under the acetabulum and femoral head, the union between the divided fragments of the femoral shaft and the position of slight abduction, to prevent the development of a subsequent knee deformity.

## RESULTS

Of 12 cases treated by the Colonna method, what may be called good end results were obtained in 8. The patient must be a good operative risk for this procedure. The chronologic age need not be a deterring factor. The patient must, in the surgeon's judgment, be able to withstand a good amount of surgical trauma. The fracture site should show definite absorption of the femoral neck or head; the less femoral neck remaining, the easier the operation and the better the result. This method can also be considered in cases in which the head of the femur is dead. Arthritic changes in the hip are not conducive to a good result with this type of reconstruction, and therefore rule out this operation.

The following facts were noted in the 8 cases treated successfully by the Colonna method. The bed and hospital confinement was shorter than that by any of the other methods used. The average was six weeks in bed; the patients spent another two weeks up and about the ward before discharge. Patients left the hospital under their own power with the aid of a crutch or cane, depending on their confidence and readjustment ability. The average shortening in these cases was less than 2.5 cm.: 1.9 cm. in 3 cases, 2.5 cm. in 4, and 3.8 cm. in 1. This shortening was of no material consequence; it could be corrected by a slightly raised heel. Internal and external rotations at the hip were quite limited; abduction ranged from 25° to 45°, and adduction from 20° to 25°. The flexion at the hip was good, and extension was normal. Patients could stand alone on either leg. They had painless hips and could walk ordinary distances without fatigue or discomfort, although with a slight limp. They had, however, some social and physical discomforts. They complained of inability to put stocking and shoe on the affected leg, and protracted sitting, such as that at the card table or the theater, caused a sense of stiffening and discomfort in the affected hip.

To arrive at this result, the patient must go through a fair amount of severe surgical trauma, but the period of hip and leg fixation is comparatively short, as are bed confinement and hospitalization, which are important items when one knows, as in other procedures, what prolonged fixation and bed treatment will do to a patient locally and generally. This period of immobilization is also a significant factor from an economic standpoint, which today is the concern of both patient and hospital.

Of 7 cases in which the Magnuson operation was employed, good end results were obtained in 4. This method should not be considered in cases

complicated by arthritic changes, or by any suspicion of cartilage degeneration or irregularity, or in cases in which the head of the femur is dead. I also believe that in ununited fractures of over one year's duration, or in cases in which no femoral neck is left, the patients are poor risks for this operation. In my experience, this procedure requires a very careful selection of cases. It involves somewhat more surgical trauma than the Colonna method. The fixation of the hip and leg and the bed confinement were quite long in these cases—ten to sixteen weeks. The patients left the hospital from the end of the tenth to the eighteenth week, under their own power and using crutches or an ambulatory Thomas splint and cane. They were bearing direct weight on the affected hips from the sixth to the ninth month. At that time, there was solid union of the reconstructed neck and head, and the hip joint was 90 per cent and more normal—as nearly normal as one could expect from a reconstruction.

The poor results in 2 cases were unfortunate. Neither fracture united. There was absorption at the reconstructed site soon after the operation. Both patients were over sixty years of age, chronologically and physically. The ununited fractures were of twelve and sixteen months' duration. One of these patients has since died, and the other is up and about as a crutch invalid but has a painless hip.

These cases have caused me to avoid the Magnuson method in ununited fractures of over twelve months' duration and in elderly people. Two of the successful cases were also benefited by these failures in that I not only chose them more carefully but, in addition to the reconstruction, did Bozsán's<sup>10</sup> hole drilling and crammed in some bone chips at the reconstruction site.

Bone grafting and allied methods were employed in 3 cases. The selection of ununited hip fractures for bone grafting, bone chips and hole drilling must be made early and with due care to the general condition of the patients, who must be above average physically to withstand successfully the prolonged spica and bed confinement. The femoral heads should be in good condition, and some of the neck should remain. Here again, those patients with arthritic changes or tendencies, or with any joint irregularity, should not be selected for these procedures.

In the 3 successful cases, the ununited fractures were of six and a half to eight months' duration. The femoral heads were all in good condition, and a fair amount of femoral neck remained. In 1 case, a simple, thorough cleaning out of the fibrous tissue between the head and neck was done, and the resulting gap was crammed

with bone chips. The 2 others had not only the hole drilling, as advocated by Bozsán, but also inlay grafts and bone chips. In these cases, spica fixation was maintained from twelve to sixteen weeks, and hospitalization lasted fourteen to eighteen weeks. All these patients left the hospital wearing protective ambulatory splints and using either a crutch or a cane. The time of direct weight bearing averaged from six to eight months. The knee joints in the affected legs in 2 of these patients lengthened the convalescence and delayed return to normalcy. The third patient had limited knee motion at operation, and this limitation persisted. The hips in the 3 patients had practically normal range of function, which was better than that in the successful Magnuson cases.

The simplicity, ease and nonshocking quality of these allied methods impressed me markedly and made me aware that early recognition of nonunion and early decision to use stimulating therapy should be sought.

The hip-fusion operation was performed in 3 cases. This method has been employed only in those ununited cases in which definite arthritic or other joint changes are shown. Again, my experience is limited, but it has been most satisfactory. Successful end results were obtained in 2 cases, and in another a successful outcome followed a secondary stimulation.

Of course, the successful end result is a stiff hip with social and physical discomforts very similar to those after a good Colonna end result — at least, that is how I have viewed it. To attain this result, the patient must go through severe surgery and a protracted spica fixation and hospitalization, varying from twelve to sixteen weeks. These are serious factors that one must face before selecting such a procedure, which is so tempting because the percentage of failures following its use is lower than that for any of the other present-day methods.

At the Boston City Hospital, 8 ununited hip fractures have been reconstructed by the McMurray osteotomy. Of these, 2 have been done too recently for the result to be judged. Five of the remaining 6 cases have gone to clinically good end results, and 1 patient, although not an absolute failure, still has to use crutches after six months. This simple osteotomy method obviously entails less surgical trauma than the other methods and, hence, less surgical shock. Thus, some cases that are deemed poor surgical risks for the Colonna, Magnuson or fusion operation may qualify for the McMurray method. However, the last is not well adapted to the following types of cases: those in which the femoral head is disintegrating; those in which the femoral neck has been absorbed and

the shaft is riding high; and those in which the nonunion is not too old and the absorption has not progressed too far and in which a simple local bone-stimulating, or the Magnuson, operation seems indicated. Successful end results by these methods give almost 100 per cent return to normalcy and have stood the test of time, which may change some present thoughts on the McMurray osteotomy.

In the few cases done by this method at our hospital, the following data have been gathered: the patients have plaster-of-Paris spica fixation from eight to fourteen weeks, and hospitalization from ten to about seventeen weeks; they generally leave the hospital using crutches but soon thereafter omit them and use only a cane, with a good clinical end result; they still use a cane in going up stairs, limp slightly, but have no local hip pain or tenderness on walking, sitting or lying down; the shortening varies from 2.2 to 2.6 cm.; there is a limited degree of internal, but a good degree of external rotation at the reconstructed hip, and also a good abduction and adduction range; there may be occasional local stiffness; the patients can dress themselves in normal fashion, cross their knees and sit for protracted periods with ease and comfort. In short, a good 80 to 85 per cent return to normalcy is usually obtained.

At present the McMurray osteotomy seems adaptable to a greater variety of the painful ununited femoral-neck fractures than the other methods. The other points in its favor are its simplicity of execution, the production of less surgical shock and, lastly, the fairly high rate of good end results showing a very creditable percentage of return to normalcy.

However, I am still firmly convinced that if an unmistakable diagnosis of nonunion could be made in the early months following the initial reduction and fixation, more of the simple bone-stimulating or Magnuson operations could be performed. I also believe that the Colonna method still has a place in cases in which there has been much degeneration of the head or considerable absorption of the neck, with the shaft consequently riding high.

The fusion operation (possibly of the Britten type) should be reserved for the failures of the other methods and for the markedly arthritic types. I hesitate to do fusion in the very old, because of their extreme slowness to adapt themselves to the limitations of a stiff hip.

\* \* \*

In conclusion, I must emphasize the fact that although each method described has its distinct uses and advantages, — the McMurray probably more than any of the others, — what I said in 1940

still holds true there is no universal method of reconstruction of painful ununited femoral neck fractures, I agree with Brackett's<sup>5</sup> statement that the surgeon's choice of procedure is still paramount

## MEDICAL PROGRESS

### SURGERY OF THE AUTONOMIC NERVOUS SYSTEM

#### Method of Study, with Particular Reference to the Interpretation of Clinical Results

REGINALD H SMITHWICK, MD\*

BOSTON

TO determine the effect of autonomic nervous activity on the peripheral circulation, in both health and disease, as well as before and after operations on the sympathetic nervous system, various methods of study are available. Some involve simple tests, such as surface temperature determinations. More complicated measurements not available to all, such as those by the plethysmographic method, are frequently used. By this procedure, the number of cubic centimeters of blood passing through a unit volume of tissue per minute can be determined. Autonomic nervous impulses that are capable of modifying peripheral blood flow can be temporarily interrupted by procaine hydrochloride block. Thus, sympathetic pathways to the blood vessels of the extremities can be inactivated by the injection of the proper segments of the sympathetic trunk paravertebrally, by peripheral nerve block or by spinal anesthesia. The last, of course, applies only to the legs. Other methods of inhibiting vasoconstriction, such as heating the trunk to promote reflex vasodilation, can be used. Of particular concern are the vasoconstrictor pathways, with which man is so abundantly supplied. These are active under many everyday circumstances, as in response to cold, pain, emotion and the upright position. When activated, the sympathetic nervous system greatly reduces circulation to the extremities, as well as to the viscera, both in the presence and in the absence of vascular disease.

The state of activity of the autonomic nervous system is very dependent on environmental temperature. For this reason, controlled room temperature conditions are essential to a study of patients both before and after operation. If the patient is placed in a cool environment for a given period, with a minimum of the body surface covered, vasoconstriction is induced. The surface temperature of an extremity is then measured, or the quantity of blood flowing through a given segment is determined by the plethysmographic method. The vasoconstrictor fibers are then temporarily interrupted by one of the methods mentioned, and the surface temperature or quantitative blood flow is again estimated. One can thus tell fairly accurately how much the circulation can be increased after sympathectomy. Certain exceptions to this statement need not be discussed at this point. It is essential that the same conditions of study be used in subsequent observations.

When patients are studied in a warm environment, vasoconstriction is not induced, and may be totally absent, in fact, in higher temperature ranges, vasodilation may actually be present. Under such conditions of study, the circulation of the extremities is not primarily dependent on vasoconstrictor activity. When judged in this manner, the blood flow to the skin and subcutaneous tissues after acute denervation by procaine hydrochloride block or actual surgical excision of the sympathetic nervous system may not be significantly altered. In fact, the maximal blood flow to an extremity is somewhat decreased by sympathectomy because vasodilator, as well as vasoconstrictor, fibers are interrupted.

Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress Annual 1940* (Springfield Ill) no 5 Charles C Thomas Company 1941 \$4.00.

\*Instructor in Surgery, Harvard Medical School assistant chief surgeon, Massachusetts General Hospital.

Thus, if one compares the surface temperature of a denervated extremity and a normally innervated extremity after exercise or after the trunk has been heated to promote reflex vasodilation in the extremities, the normally innervated extremity is the warmer. The circulation of the sympathetomized hand is nevertheless high and adequate. If, then, the patient is again observed in a cool environment, or if while he is still in a warm environment, stimuli are utilized that generally invoke vasoconstriction, such as a loud noise, immersion of an opposite extremity in cold water, or an unpleasant thought, the findings are quite different. The denervated extremity maintains its high blood-flow level, whereas the circulation of the undenervated extremity generally is greatly decreased. Operations on the sympathetic nervous system, therefore, do not increase blood flow beyond its maximal level; they stabilize blood flow near and somewhat below this point. Because the action of the autonomic nervous system in the everyday life of the average person is preponderantly in the direction of vasoconstriction, the net result of inhibiting this mechanism is an increase in blood flow to the part.

This point may be more clearly illustrated by the case of a young woman who suffered from Raynaud's disease. I had occasion to sympathetomize one of her upper extremities before she went to Europe to compete as a member of the American Olympic Ski Team. Under virtually all circumstances, the denervated hand was much the warmer. The only exception was noted after the patient had climbed to the top of the course, which required considerable physical effort. At this point, the undenervated hand was the warmer. It was also pink and moist. The denervated hand, however, was also warm and of good color, and dry. At the same time, the body was uncomfortably warm, and conditions for reflex vasodilation were present. By the time that she reached the bottom of the incline and the end of a race, however, the undenervated hand was cold and ischemic whereas the denervated hand was warm and of good color, as before the race. At this point, the body was chilled, and together with the excitement associated with the event, conditions inducing vasoconstriction were present. There was no question whatsoever in her mind concerning which hand had the better circulation day in and day out, and needless to state, the other extremity was subsequently denervated.

When, on the other hand, one is dealing with impaired circulation in the presence of known organic vascular disease, the ability of blood vessels to relax in the acutely denervated state may be already lost. In many cases, their ability to

constrict in response to nervous impulses is still preserved and can be abolished by proper surgical maneuvers. It therefore becomes increasingly imperative to stabilize blood flow at the highest possible level. That this may result in a striking increase in circulation, even in the presence of extensive obliterative vascular disease, is clear, provided one studies the patient before operation under conditions when vasoconstriction exists, and duplicates the same conditions for postoperative comparison. This seems to me to be the crux of the situation, and it is important enough to warrant a specific illustration.

Figure 1 presents the surface-temperature charts of a sixty-one-year-old man who was known to have peripheral arteriosclerosis, with obliteration of main-vessel pulsation below the femoral artery of one extremity. The other extremity also had calcified vessels, but main-vessel obliteration did not exist. Intermittent claudication of moderate severity was present in the more affected leg. After exposure of all four extremities for one hour at a room temperature of 68°F., with the patient in the horizontal position, and the body covered only by a sheet and a thin cotton blanket from axilla to groin, surface-temperature readings were taken. These were recorded at numerous points from the tip of the toe to the groin, as illustrated. The nature of the surface-temperature curves of the two extremities was similar in the undenervated state. There was no significant difference, in spite of the obvious difference in main-vessel pulsation. This type of curve, in which the surface temperatures began to fall from a high point in the extremity to the tip of a digit, indicates an unusual degree of vasospasm in response to environment. It is seen in both the presence and the absence of organic vascular disease. It is to be contrasted with surface-temperature levels in other patients with and without obvious vascular disease, in which cooling of consequence under the same conditions of study is confined chiefly to the distal portion of the foot or even to the digits only. This matter was recently discussed in greater detail.<sup>1</sup>

After exposure for one hour, the vessels of the lower extremity were acutely denervated by induction of spinal anesthesia with ensuing complete motor and sensory paralysis extending to the midthoracic level. The response of the two extremities was quite different. The surface temperatures of the extremity without main-vessel obliteration rose in a far more significant fashion, particularly in the more distal portions of the leg. On the more affected side, the surface temperature of the tip of the digit rose 5°F., and at the base, only 2°F. This was accompanied by im-

provement in color, the extremity being pink and dry by contrast with the cold, cyanotic, moist state of the tissues associated with collapsed veins and clinical signs of vasospasm, which existed in the undenervated state. These findings, together with the nature of the surface-temperature chart, indicated a worth-while result from sympathectomy.

In this case, intermittent claudication was relieved in spite of the continued absence of main-vessel pulsation. This indicates a favorable effect on the circulation to skeletal muscle, as well as the obvious increase to the skin and subcutaneous tissue. In addition, the characteristic distribution of anhidrosis involving the entire leg after

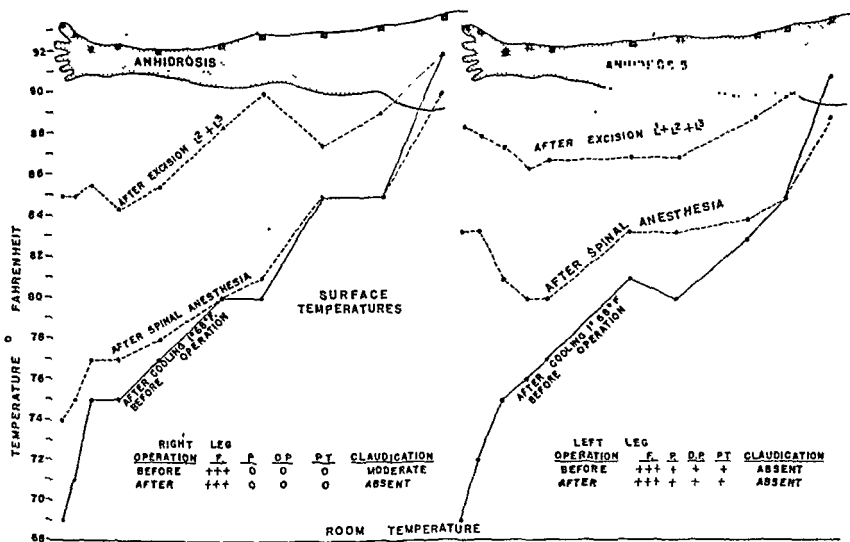

FIGURE 1.

Surface-temperature readings on both lower extremities of the same patient are compared after exposure to a room temperature of 68°F. for one hour. All four extremities were exposed, and the trunk was covered only by a sheet and thin cotton blanket from the axillas to the groin, to promote vasoconstriction. The patient was in the horizontal position. The degree of main-vessel obliteration differs in the two extremities. The effect of acute denervation following spinal anesthesia is compared with the change noted after surgical removal of certain lumbar sympathetic ganglia.

tomy in the more affected leg. There was, of course, no doubt that the circulation of the lesser involved extremity could be improved by operation, but that was not the patient's chief problem.

After operation, in response to cooling for one hour at 68°F., the surface temperatures remained much higher and were similar in the two extremities. It may therefore be stated that the circulation was significantly increased because vasoconstriction in response to prolonged cooling no longer took place. However, this does not mean that the circulation is greater in a warm environment after sympathectomy than it was before. In fact, the opposite is undoubtedly so. The one point that I should like to emphasize is that by interrupting vasoconstrictor pathways, one hopes to increase blood flow by stabilizing it somewhere near its maximal point. It should also be noted that in

excision of the first, second and third lumbar ganglia was indicated in the chart of the left leg after operation. On the right side, the removal of the second and third lumbar ganglia resulted in anhidrosis of the posterior thigh and the lower leg from the tibial tubercle distally. Figure 1 also emphasizes a clinical fact that has long been recognized: the effect of acute denervation of the blood supply to the extremities by procaine hydrochloride after exposure to and while in a cool environment does not, in the presence of the more advanced stages of obliterative vascular disease, indicate with accuracy what the effect of actual excision of appropriate portions of the autonomic nervous system will be.

This preliminary discussion of methods of study is given to present one viewpoint by which the effect of denervation of blood vessels on the

circulation of various organs and tissues of the body may be judged. I re-emphasize the fact that a quiet environment, absence of fear or worry or pain, the horizontal position and controlled room-temperature conditions are required for basal conditions of study.

#### EFFECT OF SYMPATHECTOMY FOR RAYNAUD'S SYMPTOMS

Failure to observe these fundamental rules may be the cause for differences of opinion regarding the effectiveness of sympathectomy for various disorders, and may result in erroneous deductions and conclusions. This seems to me to be part of the explanation for the conclusions reached by Johnson<sup>2</sup> in a recent article in which he finds that sympathectomy is ineffective in the treatment of patients with Raynaud's symptoms. Other reasons for the poor results that he reports will be discussed subsequently. His conclusions are based on operations performed on thirteen upper extremities and two lower extremities of 6 patients. The studies on which his conclusions are drawn are the comparison of finger volume as measured by a plethysmograph before and after operation, and at times in response to local heat, and at times in response to novocaine block of the median nerves. The conditions under which the experiments were carried out are not described. No mention is made of the position of the patient, the manner in which the body was covered or the time allowed for adjustment to whatever environment was chosen before the tests were made. The room temperature is given in three of sixteen figures and varied from 23.5 to 27.3°C., or 74.3 to 81.1°F. This clearly indicates that the conditions for study were variable and not the sort to activate peripheral vasoconstriction.

From an analysis of the figures illustrating the article in question, it is clear that the surface temperatures of the digits were high in the studies carried out before operation. They varied from 24.6 to 34.2°C., or 76.3 to 93.6°F. After operation, they tended to be slightly higher. It is therefore obvious that these patients were not studied under conditions in which the autonomic nervous system was more than partially active. Particularly I refer to Figure 14 in Johnson's<sup>2</sup> article, in which finger-volume measurements were made when the digital surface temperature was 34.2°C. (93.6°F.) before operation for comparison with the state of affairs after operation. Under such circumstances, vasoconstriction is impossible and does not exist, and sympathectomy could not and does not result in an increase in surface temperature or blood flow. The point is not that sympathectomy does not increase peripheral circulation above its maximal preoperative level. The question is,

Does sympathectomy prevent or modify a mechanism for reducing blood flow under the many conditions under which vasoconstriction exists? The answer is, In properly selected cases, the denervated extremity has a greater circulation under conditions when vasoconstriction ordinarily exists than the normally innervated extremity. This holds for normal extremities, for so-called "vasospastic disorders" and also, not infrequently, when organic vascular disease is the critical factor, such as arteriosclerosis, arteriolar disease and thromboangiitis obliterans. As organic vascular disease progresses, the maximal level of blood flow in the relaxed state decreases. The abnormal vessels, however, may still maintain their ability to constrict in response to nervous stimuli in a striking fashion. Under such circumstances, the need for modifying this latter mechanism assumes increasing urgency.

As further evidence of the ineffectiveness of sympathectomy, Johnson presents data showing that the vascular responses of an extremity to locally applied heat are not materially altered by sympathectomy. That increased blood flow to the extremity in response to local heat is controlled by local metabolic demands and not by the nervous system was shown by Freeman<sup>3,4</sup> years ago.

#### SURGICAL TECHNIC, WITH PARTICULAR REFERENCE TO DENERVATION OF UPPER EXTREMITY

It has long been recognized by many that the clinical results of postganglionic sympathectomy are not satisfactory because attacks of vasospasm recur after a few weeks, even in the absence of obvious local vascular disease, but particularly if such disease is present. Such attacks will occur in response to cold and also in a warm environment in response to emotion, such as might result from the demonstration of a patient before a group of physicians or students. The cold factor is eliminated under such circumstances. I have believed, and most observers have agreed, that this was probably the result of the action of circulating vasoconstrictor substances, and adrenin and sympathin appear to be likely ones.<sup>5-7</sup> After the preganglionic type of sympathectomy, the clinical results are far superior; such episodes as those described above in response to emotion do not occur, and vasospasm in response to cold appears only in the presence of significant degrees of local vascular disease. The attacks are milder, however, the recovery time is shorter, and the degree of exposure necessary to precipitate an attack is greater.

It is not surprising, therefore, on further perusal of Johnson's<sup>2</sup> article concerning the ineffectiveness of sympathectomy for Raynaud's symptoms, to find evidence of local fault of consequence in

some of the cases, but more particularly to find that the majority of the operations were of the postganglionic variety, which I discarded about ten years ago. In 2 cases, a preganglionic type of operation described by me<sup>8,9</sup> in 1936 and modified several times since was used. That the denervation was not complete in 1 of these cases seems possible from the response to postoperative peripheral nerve block, although as mentioned above, the surface temperature level before nerve block was so high (91°F.) as to make it impossible to draw any accurate deductions. Evidence of the presence of intact vasomotor fibers in 2 of the 3 cases in which postganglionic operations were performed is also present in Johnson's data. He prefers to ignore this, and to endow somatic nerves with a vasomotor function, to explain postoperative responses that are the result of either incomplete interruption or regeneration of the vasomotor fibers. His attempt to explain a fall in temperature in the fifth finger after median-nerve block on the basis of shunting of blood from this finger to those supplied by the median nerve is far less convincing than the suggestion that this response is due to reflex vasoconstriction in the unblocked fifth finger as a result of the discomfort or excitement attendant on the nerve block. A transient fall in temperature of the first three fingers is commonly noted during ulnar-nerve block, and of all five fingers and more proximal portions of the hand forearm and arm following paravertebral novocain block. Later, all denervated fingers reach the same high surface temperature unless the degree of local fault is more marked in some.

Atlas<sup>10</sup> has discussed the role of the second thoracic segment in the innervation of the upper extremity on the basis of a case in which this segment was not decentralized when a preganglionic type of sympathectomy was performed. He suggests that removal of the second thoracic ganglion alone is necessary to denervate the upper extremity. In this contention, he is correct. From personal observation of a number of cases in which the second thoracic ganglion was not excluded for one reason or another, it is clear that in the majority of patients, but not all, the second thoracic segment supplies fibers of consequence to the brachial plexus. However, division of the trunk above the second dorsal ganglion, with or without excision of this ganglion, excision of the second and third dorsal ganglia, and excision of the first and second dorsal ganglia have all been followed, in my experience, by significant regeneration. I have no reason to believe that simple excision of the second dorsal ganglion, which Atlas suggests as a method of denervating the upper extremity, will prevent regeneration. This major problem is recently discussed in detail.<sup>11</sup>

#### PHYSIOLOGY—BLOOD FLOW, WITH PARTICULAR REFERENCE TO HYPERTENSION

In a series of four articles, Wilkins and Eichna<sup>12-15</sup> have studied blood flow to the forearm and calf in great detail. The conditions for study were well standardized in all observations. Measurements of blood flow were made by means of a segment plethysmograph. The primary purpose of the study was to gather information concerning the peripheral circulation in cases of essential hypertension. In particular, the authors wished to determine whether the increased peripheral resistance to blood flow is due to an irreversible type of change in the walls of the arteries. Furthermore, they wished to gather more information concerning the role of the sympathetic nervous system in regulating the peripheral resistance to blood flow in both normal and hypertensive patients. In these studies, blood flow was determined in normal subjects, in patients with vasomotor disorders and in hypertensive patients. The response to various stimuli designed to activate the autonomic nervous system was observed. The effect of inactivation of the nervous system by nonoperative and operative intervention was determined. The findings are presented in detail and in such fashion that those interested in this matter will find a large number of valuable data.

These authors observe that in the forearm and calf, reflex vasodilation on warming and reflex vasoconstriction on cooling of the body are mediated by the sympathetic nervous system. It is therefore apparent that the changes in circulation in the more muscular portions of the extremities are qualitatively similar to those in the hands and feet, although they are quantitatively not so great. These reflex changes in the more muscular areas are abolished by preganglionic sympathectomy, and blood flow is stabilized at a point somewhere between the high and low levels observed in the undenervated state. As pointed out above, the blood flow in the deeper tissues is likewise reduced after preganglionic sympathectomy when compared to the maximal and increased when compared to the minimal blood flow levels observed in the undenervated state.

It is of interest that blood flow to the muscular areas of the extremities increased after sympathectomy in response to exercise exactly as it did in the undenervated state. This increase was also observed following reactive hyperemia induced by a five minute period of circulatory arrest. Moreover, blood flow to these areas increased in response to local heat after sympathectomy as before, although at the temperature level selected (40°C) the increase after operation was not quite so marked. It is therefore quite clear that certain

major physiologic responses are preserved in the denervated state, and that the necessary stimulus for their initiation is derived primarily from the tissues. A delayed vasodilator response generally induced by mental arithmetic was noted both before and after sympathectomy. This was similar to that resulting from the administration of a small amount of epinephrin. In 2 hypertensive patients, this response disappeared after adrenal denervation resulting from bilateral splanchnic and lumbar sympathectomy; it is interesting that it disappeared both in the denervated calves and in the undenervated, normally innervated arms. Muscular blood flow, which was also studied in the presence of disturbed thyroid activity, was found to vary in the same direction as the metabolic rate.

Reactive hyperemia blood flow was measured in normal and hypertensive patients. A direct relation between arterial pressure and blood flow was found in both denervated and undenervated extremities of normotensive and hypertensive patients. When the same conditions of vasodilation were imposed, there was no significant difference between the blood flow to the forearm and calf in certain normal subjects in whom rises in arterial pressure had been induced and that in certain hypertensive patients; nor was there any difference between the blood flow to the forearm and calf in certain hypertensive patients whose arterial pressures had been lowered and that in normal subjects with the same arterial pressure.

Wilkins and Eichna find their data consistent with the view that in certain hypertensive patients the blood flow to the forearm and calf during controlled vasodilation is greater than the normal for those subjects. Their study has raised doubts in their minds concerning the validity of previous conclusions that in patients with essential hypertension the vessels of the muscular segments of the limbs are involved in a generalized increased peripheral resistance that cannot be released by physiologic vasodilatation.

A series of very valuable articles and monographs has been written by Smith and his co-workers<sup>10-21</sup> in recent years concerning renal blood flow in hypertensive patients. They have devised an accurate method for measuring the quantity of blood flowing through the kidneys per minute by means of inulin and Diodrast clearances. They have demonstrated clearly that the autonomic nervous system, when activated either by pain or by emotion in the horizontal position, reduces blood flow through the kidneys by constricting the afferent arterial supply. They have also shown that renal blood flow is reduced by nervous control when the patient shifts from the

horizontal to the upright position; this is likewise due to constriction of the afferent arterioles. They also find that adrenin is capable of reducing renal blood flow but acts principally on the efferent arterioles. They observed that renal blood flow was maximal in the horizontal position, and was not increased by acute denervation of the renal blood supply resulting from spinal anesthesia. It seems reasonable, therefore, to hope that if the sympathetic nerve supply to the kidneys and adrenal glands is thoroughly interrupted by a surgical procedure, renal blood flow will be more stable and increased by comparison with the low levels resulting from vasoconstriction due to intermittent nerve impulses and reflex adrenal secretion. One would not expect it to be increased by comparison with maximal blood-flow levels in the undenervated state. Since the renal blood-flow level is almost always reduced in the hypertensive state by comparison with the normal, it is essential to stabilize and if possible to preserve what remains.

#### CLINICAL RESULTS, WITH PARTICULAR REFERENCE TO SURGICAL TREATMENT OF HYPERTENSION

Further reports of the clinical results of surgical intervention on the autonomic nervous system for essential and malignant hypertension have appeared in the literature. The operations devised vary considerably in extent. Also, the percentage distribution of cases in the different stages of the disease, as judged by eyeground changes, varies a great deal in the reported series. For example, Allen and Adson<sup>22</sup> employ an operation in which the nerve supply to the splanchnic bed is interrupted as completely as possible by an exposure that is entirely below the diaphragm. In a series of 224 patients, grouped according to eyeground changes, 5 per cent of the cases were in Group 1, 61 per cent in Group 2, 31 per cent in Group 3, and 3 per cent in Group 4. They found a significant reduction of blood pressure in 45 per cent of cases in Group 1, 35 per cent in Group 2, 26 per cent in Group 3, and 0 per cent in Group 4. For the groups as a whole, 31 per cent of the patients had a significant lowering of blood pressure.

Peet, Woods and Braden<sup>23</sup> report their experience with the supradiaphragmatic technic in which the operation is confined to the region immediately above the diaphragm. Its purpose is similar—to denervate the splanchnic bed as completely as possible by interrupting the portion of its nerve supply that is accessible at this level. The authors believed that the majority of their patients (70.7 per cent of 290 patients followed nine months to seven years) had a significant

lowering of blood pressure. Of these 290 cases, it appears that more significant evidence of lowering of blood pressure occurred in 19.3 per cent. These cases were not classified into groups according to eyeground changes. It is therefore impossible to discern the relative effect on blood pressure in the various stages of the disease. The eyeground changes were given in a series of 219 cases. In 10, the eyegrounds were normal, 13 were in Group 1, 50 in Group 2, 105 in Group 3, and 42 in Group 4. One may infer from this that the majority of the patients were in the more advanced stages of the disease.

More recently, Woods and Peet<sup>24</sup> have compared the mortality rate in 76 cases followed from five to seven years after operation with that described by Wagener and Keith<sup>25</sup> for medically treated patients. The effect on blood-pressure levels for 60 cases followed nine months or more is given. Of 4 cases in Group 1, the blood pressure was reduced in 1 (25 per cent), and of 9 cases in Group 2, a reduction occurred in 2 cases (22 per cent). Blood-pressure reduction was noted in 15 (48 per cent) of 31 cases in Group 3, and in 7 (44 per cent) of 16 cases in Group 4. The latter figures are encouraging, but the results in the cases in Groups 1 and 2 are not. Woods and Peet found the survival period in cases in Groups 1, 3 and 4 to be higher than that reported by Wagener and Keith. They noted, however, that in Group 2, the survival period was higher in the medically treated cases. The explanation for these findings is not clear. It is suggested that the significant fact was that patients in Group 2 were those with well-defined arteriolar sclerosis, without angiospasm of the retinal vessels. It is doubtful if an accurate prediction of the operative result can be made primarily on eyeground changes in the various stages of essential hypertension. Experienced ophthalmologists vary widely in their descriptions of vascular alterations in the fundi. A classification that takes into account the state of the brain, eyes, heart and kidney should be more helpful. One change about which there is no difference of opinion is the presence of papilledema. Since this constitutes the sole criterion for the diagnosis of malignant hypertension, the survival rates in Group 4 cases is significant: 33 per cent at the end of five years in the operated group, and 2 per cent in the medically treated group.

Experiences with supradiaphragmatic, subdiaphragmatic and combined lumbodorsal splanchnicectomy<sup>26</sup> were discussed by de Takats et al.,<sup>27</sup> who found the latter operation to result in a more significant lowering of blood pressure. Heuer and Glenn<sup>28</sup> report the late results of experiences with the surgical treatment of hypertension in 57 pa-

tients. Three operations were used—laminectomy, with anterior-root section, and supradiaphragmatic and subdiaphragmatic splanchnicectomy. In the opinion of the authors, the results justify a continuation of surgical attempts to relieve hypertension, but the operation should be extensive. They favor combined lumbodorsal splanchnicectomy because it is more complete than laminectomy and anterior-root section, which had to be abandoned because of the high mortality and incidence of serious complications. However, the best results, when judged by persistent lowering of blood pressure, appeared to follow this operation.

Corcoran and Page<sup>29</sup> report the effect of lumbodorsal splanchnicectomy on renal blood flow in 2 cases. There was no immediate increase; in fact, there was a decrease in both. The authors considered the effect on blood pressure to be significant, however, and suggested that in time this might result in a regression of vascular disease generally and in the kidney as well, and might, in this way, exert a favorable effect on the renal humoral mechanism.

Lumbodorsal splanchnicectomy,<sup>30</sup> which was devised more than three years ago, has been used during this period. It appears to have the advantages of both the supradiaphragmatic and subdiaphragmatic procedures, and is a little more extensive than both combined. The early results have been reported in a preliminary fashion<sup>1,30</sup> and will be given in detail this year. The operation affords excellent exposure of the kidneys and adrenal glands. Considerable information concerning the actual state of the renal blood vessels in various stages of the disease has been obtained from a study of renal biopsies. A preliminary report of these findings was made by Castleman et al.<sup>31</sup> In some cases, quantitative studies of renal blood flow have been made by Talbott.<sup>32</sup> It is hoped that these data when correlated with other detailed studies will help in the selection of cases for surgery.

Early experiences with total and nearly total sympathectomy performed in closely approximated stages in a small series of hypertensive patients were reported by Grimson.<sup>33</sup> The rationale was based on experiences with experimental hypertension in dogs. It seemed to me<sup>34</sup> that the indications for extending the surgical approach to hypertension in man beyond the splanchnic area should depend on a careful evaluation of the results of the latter maneuver and not on the results of experimental surgery. Although certain patients may benefit by greater than radical splanchnicectomy, it is doubtful if such an operation should, at present, become a routine primary procedure.

It seems quite clear that surgery has something worth while to offer the hypertensive patient. It appears that, if consistent results are to be obtained in similar cases, radical denervation of the splanchnic bed is necessary. It is also obvious that when cardiac and renal functions are both significantly impaired, operation is of no avail, however extensive. Only an occasional patient over fifty years of age is suitable for operation. When the indications for operation are clearly defined, it is to be expected that a high percentage of carefully selected patients will benefit, as judged by persistent and significant lowering of blood-pressure levels. Regression of eyeground changes, decrease in the size of the heart, improvement in the electrocardiogram, improvement of renal function and at times, of renal blood, and relief of symptoms are noted in certain cases and present additional ways of evaluating the results of surgery. Furthermore, time may show that life expectancy is increased. There can even now be no doubt of such an increase in cases of malignant hypertension and in patients with severe retinitis who have been subjected to adequate surgery before cardiac and renal functions have been seriously impaired. At the present time, surgery appears to offer the greatest hope for these patients. Perhaps, some day, a simpler solution will be attained.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28151

#### PRESENTATION OF CASE

A sixty-eight-year-old physician was admitted to the hospital because of an acute illness.

Five nights before entry, the patient suddenly lost consciousness. On regaining consciousness, after about three hours, he complained of very severe frontal headache, and vomited twelve to fifteen times within the next hour and a half. In this period he felt drowsy and dizzy. Subsequently, he was kept in bed under sedation. There was occasional vomiting. Most of the time, the patient had severe headache. There were never any paralyses, pains or respiratory difficulties.

Seventeen years earlier, the patient had an appendectomy performed in the hospital, and a year later the gall bladder was removed because of chronic cholecystitis. About two and a half years before entry, he had attacks diagnosed as "coronary thrombosis" by a physician.

On admission, the patient appeared drowsy, but co-operative and well oriented, complaining of severe frontal and temporal headache. The face was plethoric, and the pupils reacted hardly at all to light. The right fundus showed blurring of the disk and distention of the veins. The neck was moderately stiff. There was a Babinski plantar response on the right, and a questionable Babinski response on the left. There were no other abnormal reflexes, and no muscular weaknesses or sensory changes. The heart was enlarged to the left, and a harsh, rough, apical systolic murmur was audible all over the precordium.

The temperature was 98.6°F, the pulse 50, and the respirations 10. The blood pressure was 140 systolic, 65 diastolic.

The Hinton blood reaction was negative. The urine showed a + test for albumin, with occasional red and white and epithelial cells in the sediment.

An electrocardiogram showed sinoauricular tachycardia (rate 145 to 150), slurred QRS complexes, diphasic T<sub>1</sub> and T<sub>2</sub> waves, moderate left-axis deviation and a rare ventricular premature beat.

On the second hospital day, after returning to bed from the toilet, the patient suddenly cried out because of pain in his head, and lost consciousness.

There were no convulsive movements, or marked changes in color. About ten minutes later, Cheyne-Stokes respirations appeared. The patient's face turned gray, and the lips flaming red. The neck was somewhat resistant to bending forward. The right eye turned outward, and the left was fixed centrally. The heart was regular, except for slight variation with respirations (pulse 60 to 70). There was no change in the heart murmur. The lungs were clear. Suddenly, the patient became very flushed, with gasping respirations and coarse tracheal rales. The patient soon stopped breathing, cyanosis deepened, and the heart beats ceased.

#### DIFFERENTIAL DIAGNOSIS

DR MAURICE FREMONT-SMITH. There are three hurdles in this case that I may not be able to clear. In the first place, we do not have any past history, except some noncontributory data such as appendectomy and cholecystectomy, which had nothing to do with the present situation. We do know that the patient was sixty-eight years of age, was said to have had a coronary thrombosis and was, according to the history, running along well until he had this sudden difficulty.

The second hurdle is that we have no record of a lumbar puncture and examination of the spinal fluid. I assume that if a case has had a spinal-fluid examination it is a neurologic case and a neurologist discusses it, if it does not, it is a medical case and a medical man discusses it.

The third hurdle, the chief one, is the limitation of a medical man in the discussion of things neurologic.

Five days before he came in, the patient had a sudden acute episode that could be interpreted only as an intracranial accident, with the rapid development of increased intracranial pressure. He became unconscious and vomited frequently. He had severe headache. The onset was extremely sudden and, in a man of sixty-eight, suggests some sort of vascular accident; the stiffness of the neck makes one believe that subarachnoid hemorrhage was the likeliest diagnosis. On the other hand, it is unusual to have subarachnoid hemorrhage at this age. It is usually the result of congenital anomaly, and usually occurs earlier than this. Moreover, with a subarachnoid hemorrhage as with any type of meningeal irritation, fever is the rule, and this man had no fever. I remember, in discussing a case a few weeks ago, Dr Kubik brought up the fact that, with subarachnoid hemorrhage, very frequently albumin and red cells of unknown origin appear in the urine, so that we can accept the albumin in our hypothetical diagnosis of subarachnoid hemorrhage. On the other hand, further possibilities must be considered. Was

this man well, or was he having some symptoms before the onset of this acute episode? He could have had a brain tumor, and this sudden episode could have been hemorrhage into the tumor. If so, we must assume that the hemorrhage had extended into the subarachnoid space, because he had meningeal irritation. He could have had meningitis, but a meningitis is usually much slower in onset and there should be some fever. Unconsciousness would come late. Lumbar puncture would be almost essential in making this diagnosis.

The patient could have had some sort of injury. He might have fractured his skull previously; we have no history. He might have had a subdural hematoma. There again, the blood must have gone into the subarachnoid space. He might have had a subacute bacterial endocarditis with embolism to his brain. He was very old for that, but he had a rough systolic murmur. I should like some comment from the neurologist afterward. I believe it would be very unlikely to have meningeal signs from such a lesion. We have the interesting fact that the patient had no paralysis. He had a Babinski response on the right, and a questionable one on the left. So that if we try to localize it, we should assume the greater injury or difficulty on the left side of the cerebrum. On the other hand, when the choked disk was described, it was the right fundus that showed blurring, and I am unable to interpret the development of this unilateral choked disk. I believe that it must be very important. It is a very rapid development: within five days, the patient had a markedly choked disk on one side. I do not know how to explain that.

Regarding embolism from the heart, if the patient had had an old coronary thrombosis he might have had a thrombus in the left side of the heart,—a mural thrombus,—and he might have thrown that off into the brain. On the other hand, the electrocardiogram does not suggest coronary thrombosis. I should interpret the electrocardiogram as showing arteriosclerotic coronary heart disease, but without evidence of thrombosis.

It is interesting that he was allowed out of bed in the hospital after this accident. Either it was against orders or they did not think he was seriously ill. He got out of bed, walked to the toilet, had a recurrence of whatever happened to him originally, and died with increasing signs of intracranial pressure and some localized paralysis of the right eye or both eyes. I am going to ask subsequently if the neurologist will make a comment about this. I cannot understand the lesion behind that type of paralysis.

Accordingly, because he was sixty-eight years old, I believe the patient had a vascular accident of some type, perhaps a subarachnoid hemorrhage. He had a low blood pressure. Did he always have it? Was the blood pressure usually high, and did it come down either because of cardiac insufficiency or because of the shock occasioned by his recent lesion? If he had had increasing or increased intracranial pressure, the blood pressure should have risen. The blood pressure, however, was not high, but the pulse was slow; he had choked disks, and he had, I think, increased intracranial pressure. I should like to leave the case open for discussion from the floor and ask the neurologic experts to add something.

My diagnosis is intracranial vascular accident, probably subarachnoid hemorrhage. If the patient had had an intraventricular hemorrhage, I think he would have been sicker, have had convulsions, and not have regained consciousness; and I think it is more likely a straight subarachnoid hemorrhage. Without hypertension, I suppose that, even at this age, the basis for hemorrhage was a congenital aneurysm.

DR. WILLIAM B. BREED: I am not a neurologist, but I should like to ask a question. Do you think perhaps the meningeal, subarachnoid phase of this has been overemphasized? The only evidence is some stiffness of the neck, only slightly painful.

DR. FREMONT-SMITH: It is quite important evidence. One sees a patient with almost no neurologic signs, perhaps a headache, but if only slight stiffness of the neck is present one may suspect a diagnosis of encephalitis as against a simple upper respiratory infection. I think that this sign is important if present. One thing to remember is that in stiffness from meningeal irritation the neck resists forward bending, but the head can be easily turned from side to side. In arthritis, on the other hand, all motions of the head are painful. I prefer to believe that the symptom is important in this case.

A PHYSICIAN: Does it not say later that it became stiff?

DR. FREMONT-SMITH: The last note says, "The neck was somewhat resistant to bending forward." I should accept that as an important sign.

DR. TRACY B. MALLORY: Does anyone care to comment on Dr. Fremont-Smith's question regarding meningeal irritation secondary to emboli from a bacterial endocarditis?

DR. CHARLES S. KUBIK: We have had a fair number of cases in which cells, although usually no organisms, were present in the spinal fluid and a subarachnoid exudate was found on post-mortem examination. The condition presumably results

from emboli to meningeal vessels. Another possibility is bleeding from a mycotic aneurysm.

In answer to Dr. Breed's question, another point in the history must be considered. All this patient had was a stiff neck and headache, but the symptoms came on suddenly, and at the onset he lost consciousness.

DR JAMES B AYER: I saw this patient at home on the third day of his illness. He was mentally clear, admitting slight headache. Except for slight stiffness of the neck, neurologic examination was negative. The heart was as described. I believed that we were dealing with cerebral embolus and asked Dr. Paul White, who had followed him, if the heart was consistent with this diagnosis. He agreed. I saw the patient the next day. The neck was still very slightly stiff, and there was still headache. Kernig's sign was absent, and the fundi were normal. Although the diagnosis of cerebral embolus still seemed to me correct, it was decided to send the patient to the hospital for further study. A lumbar puncture was planned for the morning of his death. Had it been done before death, I should certainly have considered it a contributing factor. As it was, his unexpected walk to the toilet room seems to have been the predisposing act. The second episode naturally weakened my opinion about the diagnosis of embolus. Yet we had no evidence for tumor or any long standing disease other than that of the heart. I was reticent about making a diagnosis of spontaneous subarachnoid hemorrhage, and still favored the diagnosis of embolus.

A PHYSICIAN: I wonder if you would say a word about the ocular paresis.

DR. AYER: Yes; there was a slight paresis, which certainly was a little in favor of Dr. Fremont-Smith's diagnosis.

DR. JACOB LERMAN: Did Dr. Fremont-Smith commit himself about the heart?

DR. FREMONT-SMITH: I did say that I thought the electrocardiogram gave no evidence of prior coronary thrombosis.

#### CLINICAL DIAGNOSES

- Cerebral hemorrhage?
- Cerebral embolus?
- Old myocardial infarction.

#### DR. FREMONT-SMITH'S DIAGNOSIS

Subarachnoid hemorrhage from congenital aneurysm.

#### ANATOMICAL DIAGNOSES

Congenital aneurysm of right internal carotid artery and circle of Willis, with rupture and hemorrhage into subdural and subarachnoid space.

Cardiac hypertrophy, hypertensive type.

Infarct of heart, healed.

Arteriosclerosis, marked, generalized.

Nephrosclerosis, moderate.

Operative scars. cholecystectomy and appendectomy.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The heart was hypertrophied and showed marked diffuse coronary sclerosis. All the vessels were narrowed down to pinpoint lumens, but there were no points of complete occlusion. The left ventricle showed considerable patchy fibrous scarring of the inner third of the myocardium, consistent with old infarction, two or three years old perhaps. There was no overlying thrombus, however, and no thrombi in any of the other cavities, and there were no valvular deformities or anything to explain the heart murmur.

DR. KUBIK will describe the cerebral findings.

DR. FREMONT-SMITH: May I ask Dr. Bland if it is usual for an old coronary thrombosis to give a later electrocardiogram like this?

DR. EDWARD F. BLAND: It may be anything from normal to the findings recorded here.

DR. MALLORY, would you be willing to comment on emboli following coronary thrombosis? It often comes up in these discussions.

DR. MALLORY: It is my impression that, if an embolus occurs following infarction, it follows after a relatively brief period; in the first month, it is not unusual, but subsequent to that it is quite uncommon.

It is generally true that emboli from a mural thrombus overlying an infarct are apt to be large massive ones, not the type that might plug a small vessel in the brain. It is more apt to be an enormous embolus that goes down the aorta and forms a rider at the bifurcation of the iliac arteries or plugs the whole femoral artery on one side.

DR. KUBIK: There was a ruptured aneurysm in the outer angle between the right internal carotid and posterior communicating arteries. Although these are called congenital aneurysms, it is quite possible that they may not always date from birth. They always occur in the fork between a larger artery and one of its branches, or between two branches of the same size. It is not uncommon to find a defect in the media at this point. It is the defect that is congenital, and an aneurysm is probably an enlarged defect, which, in some cases, is present at birth but may develop, in other cases, after birth on the basis of the congenital defect. There is no media in the wall of the aneurysm, only intima and adventitia. Most of those observed in this laboratory have involved the internal

carotid, middle cerebral or anterior cerebral artery. There have, I believe, been only two of the basilar artery.

DR. MALLORY: I think it is fair to say that as we have become increasingly conscious of the relation of aneurysms of this type to cerebral accident, and particularly to subarachnoid hemorrhage, we are finding them with considerably increased frequency even in people beyond fifty, as in this case.

A PHYSICIAN: May I ask about the kidneys?

DR. MALLORY: They showed very slight contraction consistent with a slight degree of hypertension. The patient may very possibly have had hypertension before his cardiac infarct. I do not know specifically.

DR. HENRY R. VIETS: Was there much blood in the subarachnoid space, or little?

DR. KUBIK: There was a good deal.

DR. VIETS: It is interesting that he did not have convulsions.

DR. KUBIK: The hemorrhage had not extended into the substance of the brain, as it sometimes does.

DR. VIETS: We can say, then, that the stiff neck was important.

DR. ALLEN G. BRAILEY: Was not the low blood pressure an unusual finding?

DR. MALLORY: The patient may well have had a hypertension that disappeared with the cardiac infarct. That is not an uncommon story.

## CASE 28152

### PRESENTATION OF CASE

A twenty-seven-year-old housewife was admitted from an outside hospital, because of coma, following stiffness of the neck.

A week before entry, the patient awoke one morning with a stiff neck. There were no other complaints. A physician found the neck to be fairly rigid, with some voluntary spasm of the right trapezius muscle. The neck could be moved laterally without much difficulty, and could be flexed passively. The blood pressure was 145 systolic, 90 diastolic, seated. The temperature, pulse and respirations were normal.

There was no history of antecedent trauma. Ten years previously, the patient had been operated on for a benign ovarian cyst.

The neck was treated with local heat and rest. In the next three days, there was much improvement, so that the patient went to a dance, feeling well. The next afternoon, the stiffness in the neck returned, and local heat failed to help. Two days before entry, the patient again consulted her phy-

sician. Examination showed inability to flex the head because of pain and stiffness on the right side of the neck, extending upward to the right occipital region. Lateral motion was restricted on the left, but fairly free on the right. The reflexes were normal, with a negative Kernig's sign. The pupillary reactions and the fundi were normal. The temperature, pulse and respirations were normal. Bed rest, aspirin and local heat were advised. On the morning of entry, the patient complained of headache centering in the right parieto-occipital area. A cough made her feel "as if the top of the head were coming off." The pupils were small, and reacted poorly to light. She was admitted to an outside hospital, with a temperature of 98.8°F., a pulse of 68 and respirations of 20; the blood pressure was 150 systolic, 90 diastolic. Examination of the blood showed a white-cell count of 12,000. The urine was normal. The patient was put to bed, and given sedation. She dozed for an hour, then awakened suddenly and cried out in pain. The right arm and leg twitched. She was unable to speak, but seemed oriented. The pulse was 60, the respirations were shallow, and there was slight cyanosis. Oxygen and intramuscular magnesium sulfate and caffeine were given. In about three minutes, there was gradual recovery. The blood pressure was then found to be 210 systolic, 110 diastolic. The patient was fully conscious, rational and able to talk. She said that her headache had abated. She remained quiet for about two hours, when there was a second attack similar to the first. The right arm and leg twitched, and then became fixed in rigid extension, with the right foot in Babinski position. After twenty minutes, the left arm and leg progressed through a similar phase of twitching to a similar type of spasticity. The rigidity of the neck had disappeared. There were no facial twitchings. The pupils were constricted. There was continued unconsciousness. The systolic blood pressure varied between 160 and 180. The respirations were shallow, varying from 20 to 30, and even in an oxygen tent the color was dusky. The pulse remained at 60. The patient was transferred to this hospital by ambulance.

On admission, the patient was apneic, with a pulse between 130 and 150. There was some question of early edema of the medial sides of both optic disks. The patient was maintained in a respirator for about an hour, when the heart stopped.

### DIFFERENTIAL DIAGNOSIS

DR. CHARLES S. KUBIK: A young woman was admitted in coma, following stiffness of the neck of a week's duration. There was no paralysis.

If, as one may assume, the patient had been in good health, there are not many diseases that would result in such a sequence of events. One might think of meningitis and spontaneous subarachnoid hemorrhage, but meningitis ought to be ruled out by the absence of fever and by a temporary remission of symptoms. There is still another reason for ruling out meningitis. This patient did not have any headache until several days after the onset of her illness. The absence of headache, to be sure, very nearly rules out subarachnoid hemorrhage. Headache is usually the first and one of the most prominent symptoms, but there are occasional cases without headache. I have heard of two, and there is a patient in the hospital now whose headache, which was severe at the onset, quickly subsided although the neck was rigid and movements of the neck were painful, the pressure was very high, and there were signs of active bleeding in the form of convulsive seizures and increasing hemiparesis.

But, returning to the case under discussion, one week or so after the onset of stiffness of the neck the patient did complain of headache, centering in the right parieto-occipital region, and when she coughed it felt as if the top of her head were coming off. These symptoms were more typical of hemorrhage and increasing intracranial pressure. Then, shortly after being admitted to the outside hospital, she cried out with pain, which, I assume, signified a sudden increase in the severity of the headache; however, it may have been due to pain in the neck, or both. In any event, the sudden onset and severity of this pain compel one to think of bleeding, and nothing else.

From this point on, the course was more or less characteristic of severe intracranial hemorrhage, and consistent with subarachnoid hemorrhage that had broken through the pia mater into the brain or ventricle, with a marked and rapid increase in intracranial pressure. Such a situation best explains the seizures, elevation of blood pressure, slowing of the pulse, shallow respirations and, finally, respiratory failure. Toward the end, the pulse became rapid, presumably because of paralysis of the vagal centers in the medulla.

Could this have been a cerebral or pontine hemorrhage? I should think not. The patient was young; she did not have hypertension or, at any rate, not marked hypertension, and there was no paralysis.

I recall a case of cerebellar hemorrhage, with rupture into the fourth ventricle, that ran a course similar to that of subarachnoid hemorrhage. In that case, I believe, there was considerable vertigo. I mention this because of the right sided pain in the neck but have no right to offer it as a diagnosis.

The possibility of cerebral or cerebellar tumor, other than vascular tumor and of abscess or subdural hematoma can, I should think, be dismissed without any further comment.

If this was a subarachnoid hemorrhage, what and where was the source of the bleeding? By far the most common cause, as you all know, is so called "congenital aneurysm." Less common causes are varices, cavernous hemangioma, hemangioma of choroid plexus, mycotic aneurysm and hemorrhagic disease. I do not see any special reason for suspecting any of these less common conditions, and my diagnosis will therefore have to be ruptured congenital aneurysm. The violence of the terminal stage of the illness suggests arterial rather than venous bleeding.

The aneurysms, in my experience, are most often found on the internal carotid, middle cerebral or anterior cerebral arteries, occasionally on the basilar. In this case, possible leads to localization are somewhat bewildering. Rigidity of any pain in the neck, without headache, observed at the onset, might point to the posterior fossa. A small amount of bleeding there might conceivably cause considerable rigidity of the neck without increasing intracranial pressure very much. Small pupils, reacting poorly to light, also suggest a disturbance in that locality. It is a matter of experience that fixed pupils in subarachnoid hemorrhage are of no localizing value, but the pupils in this case also became constricted, and that might mean something. There were no other signs of cranial nerve involvement to help one in making a localization.

What can one do with the seizures? These began on the wrong side,—that is, on the same side as the headache,—then involved the other side, and were followed by what was probably extensor rigidity. They might suggest aneurysm of the internal carotid, middle cerebral or anterior cerebral artery, possibly the anterior cerebral, which lies in the intercerebral fissure, so that the hemorrhage might have extended first into one and then into the other frontal lobe or, what is commoner, upward through the rostrum of the corpus callosum into the anterior horns of the lateral ventricles. But if that had been the site of the bleeding, one would have expected frontal headache and pain back of the eyes. I believe that I have seen seizures such as these, and extensor rigidity as a terminal event in subarachnoid hemorrhage even when there was not extensive hemorrhage into the substance of the brain. The ventricles may even be distended with blood entering through the cistern, fourth ventricle and aqueduct. Perhaps the seizures are not of localizing significance and can be explained by an aneurysm of the basilar artery rupturing into the third ventricle. I have

that takes cognizance of the adroit and intelligent manner in which he has handled the promotion of the Society's medical-service plan in Massachusetts.

## NATIONAL FOUNDATION FOR INFANTILE PARALYSIS

THE National Foundation for Infantile Paralysis has completed three years of work since its organization. This new and active group, covering the entire field of investigation into the cause, prevention and amelioration of poliomyelitis, is supported by a fund-raising agency, the Committee for the Celebration of the President's Birthday. Through various medical committees, activities are carried out in virus and nutritional research, the prevention of aftereffects, the study of epidemics and the dissemination of educational information.

In 1941, according to the annual report,\* the largest grants for research went to the virus-research committee. A sum of over \$185,000 enabled investigators in many states to pursue their studies. Large grants were made to the School of Public Health of the University of Michigan, the George Williams Hooper Foundation of the University of California, Yale University School of Medicine, the United States Public Health Service and others. The University of Wisconsin received over \$60,000 under the committee on nutritional research. The work on aftereffects, carried on in many laboratories and hospitals, was made possible by grants totaling over \$150,000, and the fields of epidemics and education were not neglected. Thus, a total of over \$800,000 was used to combat poliomyelitis in 1941.

It is naturally impossible at this time to evaluate the results of the expenditure of such a large sum of money on the study of a single disease, particularly since many of the grants were for the continuation of studies that will not end for some years to come. One may say, however, that the work of the National Foundation for Infantile Paralysis in three years has profoundly affected present-day knowledge of the disease by making

a broad and continuous attack on many fronts. New light has been thrown on the widespread nature of poliomyelitis, the problem of the healthy carrier, transmission of the disease by flies, the retention of the virus in sewage, the entrance of the virus into the body by various routes, the use of animals other than the monkeys for experimental purposes and new means of virus identification. In the field of aftereffects, the sponsoring of the investigations of Miss Elizabeth Kenny's technic of treatment has been outstanding. In view of previous criticism of this method, the decision of the foundation to investigate was not reached without long deliberation; however, the subsequent endorsement of the Kenny treatment by the Medical Advisory Committee is proof of the value of the foundation's farsighted policies. The educational needs have been met by grants for schools of nursing, scholarships, conferences and publications. Many field studies have been carried out by the Committee on Epidemics and Public Health. In general, material advances have been made, investigation has been stimulated and new knowledge has been added to the subject of poliomyelitis by the work of the foundation.

## MEDICAL EPONYM

### NÉLATON'S LINE

Professor Auguste Nélaton (1807-1873), surgeon of the Saint-Antoine Hospital, of Paris, called attention to this line in his *Éléments de Pathologie Chirurgicale* [*Elements of Surgical Pathology*] (Paris: Germér Baillière. 2: 441, 1847). A portion of the translation follows:

If the exact relations of the great trochanter to the various bony prominences of the pelvis be examined in their normal state, it will be found that when the femur is flexed to a right angle and slightly adducted, the top of the great trochanter falls in a line that extends from the anterior superior spine of the ilium to the most prominent portion of the tuberosity of the ischium, and that this line divides the cotyloid cavity into two equal parts. This line, corresponding to the center of the cotyloid cavity . . . may easily serve as a guide to measure the degree of displacement [of the head of the femur]. . . . For this purpose, it suffices, after the thigh has been flexed to a right angle, to place a tape on the two points indicated,— that is, the anterior superior spine of the ilium and the ischial protuberance,— and to explore the gluteal region of both the sound and the injured side, to observe the difference between the two.

R. W. B.

## MASSACHUSETTS MEDICAL SOCIETY

## TREASURER'S REPORT

## COVERING REFUND DISTRIBUTION

The treasurer of the Massachusetts Medical Society makes the following report regarding the refund to district societies for 1942:

The Council voted to distribute the sum of \$4000 to district societies. The total number of payments of annual dues received by the treasurer by March 4, to be counted for the refund, was 4023. Therefore the refund to the district societies for each paid fellow is \$0.994.

The following table gives the number of payments as of March 1, and the refund to each district as of March 31:

DISTRICT	NUMBER REPORTED PAID	REFUND
Barnstable .....	41	\$40.75
Berkshire .....	108	107.35
Bristol North .....	58	57.65
Bristol South .....	163	162.05
Essex North .....	180	178.95
Essex South .....	233	231.60
Franklin .....	36	35.82
Hampden .....	293	291.25
Hampshire .....	52	51.70
Middlesex East .....	123	122.26
Middlesex North .....	109	108.35
Middlesex South .....	779	774.33
Norfolk .....	697	693.82
Norfolk South .....	122	121.30
Plymouth .....	116	115.30
Suffolk .....	492	489.05
Worcester .....	346	343.92
Worcester North .....	75	74.55
Totals .....	4023	\$4000.00

In 1941, for comparison, the total number of payments for the refund was 4038.

CHARLES S. BUTLER, M.D., *Treasurer.*

## COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: RETAINED PLACENTA FOLLOWED  
BY UTERINE AND TUBAL ABSCESSES AND DEATH

A seventeen-year-old primipara had had adequate care from the fourth month of pregnancy. Physical examination was negative, and the past history was irrelevant. Labor was complicated by a breech presentation, the labor itself being normal. The breech was delivered without difficulty. The baby weighed 6 pounds, lived only an hour, and showed numerous deformities, among them clubfeet, spina bifida and hydrocephalus.

The placenta separated in part immediately because there was considerable hemorrhage, but it did not come away spontaneously. An hour after delivery, the patient was in shock. The placenta had not been obtained, and attempts to remove it were abandoned. During the night following delivery, there was more bleeding, the blood pressure falling to 80 systolic, 75 diastolic, with a pulse of 140. On the following morning, some fragments of placenta were obtained with a placental curette. A few hours later, the placenta was expelled spontaneously. Fifteen minutes after this, the patient had a chill, the temperature rising to 106°F. A high fever persisted until death, which occurred twenty-seven days later. The patient during this septic course was transfused twice and was given sulfanilamide. Autopsy showed an abscess of the right cornu of the uterus and of the right fallopian tube, with metastatic abscesses in both lungs.

*Comment.* This infection was probably due to attempts to remove the retained placenta, which may have been slightly adherent but was certainly not an accreta, as proved by autopsy. Autopsy also showed that the infection started in the uterus and became a blood-stream infection, with localized abscesses in the lungs. The sulfanilamide therapy was probably unintelligent. There was no evidence of uterine or blood culture on which to base this chemotherapy, but the patient was treated at the beginning of the era of chemotherapy, before proper standards had been established.

Retained placentas are inherently serious complications. So long as an adherent placenta or a retained placenta is unaccompanied by hemorrhage, it is wisest to leave it alone, often for as long as twenty-four hours—in the absence of bleeding—before manual attempts to remove it. Frequently, before the end of twenty-four hours, the placenta separates itself and is delivered spontaneously. In the presence of actual bleeding, the uterus must be invaded under the strictest asepsis. In no other way may a diagnosis be made and hemorrhage controlled. A retained placenta is easily removed, and a lightly adherent placenta may be manually separated from the uterine wall and removed intact. A placenta accreta can be diagnosed only by intrauterine examination. An accreta so diagnosed demands hysterectomy.

It is always wise to pack the uterus from which an adherent placenta has been manually removed. This is done for two reasons: to guard against subsequent hemorrhage; and to hasten the separation of small areas of placenta that have not been removed.

## "THE CARE OF CRIPPLED CHILDREN"\*

The Massachusetts Department of Public Health has recently completed its first five years of Services for Crippled Children. These services were made possible by a federal grant-in-aid authorized by the Social Security Act of 1935.

During this period, more than 2000 children who probably would not otherwise have been able to receive medical and surgical care and aftercare were admitted to the ten state-wide clinics that minister to crippled children. This service has cost a little over \$400,000, including hospital care, so that the average expenditure for each child has been less than \$200.

More than 600 of the 2000 crippled children who came to the clinics needed immediate surgical help, and were at once admitted to hospitals for operation. More than 150 had to have more than one operation. One had to be admitted to a hospital six times, and another child remained in the hospital continuously for twenty months.

These crippled children came largely from rural regions where there are few opportunities for them to receive the care they need. Even so, it is a matter of surprise that so many neglected crippled children actually were found because, as compared with other states, the Commonwealth is unusually well supplied with both public and private agencies that have for years been engaged in the humanitarian work of aiding the handicapped child. In administering this program, the department has been very careful to avoid supplanting the work of any of these agencies. The purpose of Services for Crippled Children has been solely, in the words of the Social Security Act, "to improve and extend existing services."

As a result of a study of what has been accomplished for crippled children by the Department of Public Health during the last five years, several interesting things have been learned.

### AGE AND SEX OF CRIPPLED CHILDREN

More children come to clinic for the first time when they are in their sixteenth year than at any other age. If these adolescents came for help because of deformities caused by accidents or infections, one might conclude that they had been injured in their early teens, when children are on the streets more than when they are younger. But this is not so, for the great majority of patients at this age have had their disabilities for years.

The reason for not seeking aid sooner can only be inferred. That the age of sixteen is the most popular one at which to go to a clinic for help is particularly true of boys. Girls report in gradually increasing numbers beginning at the age of thirteen, through fourteen, fifteen and sixteen. One must conclude that many of the patients at the adolescent age, both boys and girls, come on their own initiative when they begin to take an interest in themselves and in their appearance. This change begins at a younger age in girls than in boys, and reaches its climax at sixteen in both boys and girls.

More than a third of all crippled children admitted to clinics came because of crippling conditions that they had had ever since birth. Most of these children were not seen until they were ten to fourteen years of age. However, the Department of Public Health has been offering this service for five years only, and many children had no opportunity to get aid earlier in life. Now that the clinics

are more widely known and have achieved considerable reputation for excellent care, such children will probably apply for treatment at younger ages.

The reasons why parents do not bring their children to clinics at younger ages are several. They realize that treatment and apparatus are expensive, they fear the surgical operations that are so often necessary, and they think that the crippling condition is so hopeless that nothing can possibly be done to alleviate it. There are also, of course, those who believe that a deformity has been bestowed by the Deity and, therefore, should not be disturbed. On the other hand, certain parents will not regard a deformity as hopeless, no matter who has told them so, and go to every clinic and to every physician who can speak with authority, in the vain hope of finding someone who will promise physical restoration.

### PROCEDURE FOR ADMISSION TO CLINICS

To be admitted to a clinic, a crippled child need only present an application signed by a physician licensed to practice medicine in the Commonwealth, preferably the family physician. A child thus admitted is given a thorough examination at the clinic, following which a complete social study of the patient's family is made by a public-health social worker. If this social study indicates that the child would be unable to obtain all the medical and surgical attention he needs without state or charitable aid, he is accepted for care. The information obtained by the social worker is also referred to the chairman of a special committee of the district medical society for an expression of his opinion concerning the child's eligibility for public care. Every effort is made to exclude from clinics all persons who are able to pay and who should pay for all the necessary treatment and apparatus. The final decision of eligibility for admission to a clinic rests with the Commissioner of Public Health. If patients can afford part of the services rendered, arrangements are made for them to pay the hospital or the brace maker.

### PHYSICAL THERAPY

Many of the patients seen at the clinics do not require operations; they may need no other treatment than physical therapy. In such cases, the clinic consultant prescribes the treatment he wishes given, and arrangements are made for the physical therapist of that clinic district to visit the home periodically to carry out these recommendations. Where there are several patients in a community who require such treatment, they are brought together, if possible, at some convenient center and are there given treatment; the time of the physical therapist is thus conserved. Such an arrangement is not often possible, for most of the patients live in rural regions at some distance from each other. To have such patients brought to a central point would require transportation and the time of some other member of the family. The mother would generally not be able to take the time to go with the child, and thus one of the most important functions of the physical therapist would be lost—that of teaching the mother or an older sister what treatment to give and how to give it.

### PREVIOUS MEDICAL AND SURGICAL CARE

Over 500 children had never had any medical or surgical treatment when they first came to a crippled children's clinic. That such a situation existed in the Commonwealth has surprised those who insisted, before the Orthopedic Unit was organized, that few neglected children would be found. In all justice to the medical

\*A "Green Lights to Health" broadcast given through Station WAAB by Dr. Edward G. Huber on Saturday, January 31, and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

profession, it must be said that the reason for the neglect of these children was not that physicians had refused to help them but that the parents had made no effort to obtain care for their children. The tendency in some families is to hide the deformed child from other than members of the family, and thus to become so accustomed to the sight of the crippling condition that all thought of making the necessary efforts to correct the condition disappears.

Several hundred crippled children had had no other help before coming to the state clinic than the advice of their family physicians. It must be remembered that these children are a rural-dwelling group and that under such conditions the family physician's help is largely limited to giving advice, since he cannot afford to provide hospitalization or apparatus. The only hospitals ordinarily available to rural patients are the smaller ones where free beds are not numerous and clinics are few. The Orthopedic Unit makes a particular effort to extend Services for Crippled Children to just such areas, to find and care for these children.

Over 300 of the clinic patients had had previous treatment in some metropolitan or local hospital. Practically all these children had had operative treatment, and this had nearly always been well done. But no matter how successful an operation, unless there is efficient aftercare and follow up, much of the beneficial effect is lost. This was true in many of the patients seen in the clinics who had had operative procedures some years before admission, but who had had no aftercare. Many of them needed another operation, which might not have been necessary if they could have had good aftercare.

Many parents brought their children to the state clinic because they had found it necessary to discontinue the treatment their children were receiving, because of lack of sufficient funds. Treatment for crippled children generally extends over several years and expensive apparatus is frequently necessary.

More than 100 others discontinued their previous treatment because they had reached the age limit established by the agency under whose care they had been. Since patients are accepted at the clinic centers up to the age of twenty-one years, this is an excellent way to fulfill one of the purposes of Services for Crippled Children—to extend existing services.

#### ACCEPTANCE OF RECOMMENDATIONS

The recommendations of clinic consultants are surprisingly well accepted. No special efforts are ever made to induce anyone to consent to operation. The risks and the possibility of unsatisfactory results, as well as the possible benefits to be derived from surgical interference, are explained to each patient's family. On the other hand, a parent's first refusal is rarely accepted as final, especially if there are good chances for improvement in that child's condition. The unco-operative patients are discharged from a clinic only after they finally and definitely refuse to accept aid, and after the clinic consultant and several members of the field staff have repeatedly talked with them.

Any patient who has been dropped from the active list because of refusal to accept the aid that has been offered may, of course, be readmitted at any time that the parent changes his mind and decides to accept aid. Occasionally, in flagrant cases of neglect, the Society for the Prevention of Cruelty to Children is called on for aid, which is gladly given. A child should not be penalized for life because ignorant parents refuse to allow him to have his handicaps overcome.

It is remarkable that only a few have refused aid. This is a tribute to the clinic consultants and to the field workers, physiotherapists and social workers alike, who interpret the orthopedists' recommendations to the families. Most of the refusals came early in the program, they are rare now that the clinics have achieved a well-earned reputation for obtaining satisfactory results.

One cogent reason for this reputation lies in the continuity of the service offered, once the patients are accepted. They are examined by the clinic consultant, who is aided by the clinic supervisor, the physical therapist and the social worker. If physical therapy is prescribed, the patients see the same physical therapist again and again. The same social worker sees them repeatedly at their homes and in clinics. When they return to clinics, they see the same physician. If an apparatus is ordered, it is fitted by the physician, who gives full instructions concerning its use and who adjusts it as need arises. The physical therapist sees that the apparatus is properly used, makes any necessary adjustments if she can, or has the patient come to the clinic for this service. If an operation is recommended, the child is not merely turned over to a strange hospital staff. The clinic physician, whom the child knows, performs the operation. A very striking result of this careful, kindly follow-up care is the attitude of patients in the clinic sessions. A child on his first visit is often apprehensive and worried, and manifests his emotions by crying and by resisting the examinations. On subsequent visits, the contrast in the child's demeanor is striking, except in permanently unco-operative children, of whom there are fortunately not many.

Almost 1000 children are now under active clinic care, but there are still almost a hundred towns in the State with a total population of about 160,000, from which no crippled child has yet been admitted to a state clinic. It is reasonable to assume that in many of these rural towns there are crippled children who are in need of care, and the Orthopedic Unit of the Department of Public Health plans to make special efforts to locate them so that they may be offered whatever help they need.

#### DEATHS

COOK—JAMES H. COOK, M.D., of Quincy, died March 28. He was in his fifty ninth year.

A native of Newcastle, Maine, he received his degree from Tufts College Medical School in 1910. He was a fellow of the American College of Surgeons and a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son, two brothers and a sister survive him.

FREUND—ERNEST FREUND, M.D., of Boston, died recently. He was in his sixty fifth year.

Dr Freund received his degree from the Medical Faculty of the University of Prague. He was a member of the Massachusetts Medical Society and the American Medical Association.

MELEDY—JOSEPH A. MELEDY, M.D. formerly of Milton, died April 1. He was in his fifty first year.

Dr Meledy received his degree from Tufts College Medical School in 1918. He was for many years a physician in the regional office of the Veterans Administration in Boston. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives him.

## MISCELLANY

RÉSUMÉ OF COMMUNICABLE DISEASES  
IN MASSACHUSETTS FOR FEBRUARY, 1942

DISEASES	FEBRUARY 1942	FEBRUARY 1941	FIVE-YEAR AVERAGE*

\*Based on figures for preceding five years.

†Meningitis, Other Forms (except Pfeiffer Bacillus) not reportable until May 13, 1941.

## GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Amherst, 1; Boston, 1; total, 2.

Diphtheria was reported from: Cambridge, 1; Everett, 1; Framingham, 1; Lowell, 3; Somerville, 1; Springfield, 1; Waltham, 1; Wilbraham, 1; Worcester, 1; total, 11.

Dysentery was reported from: Tewksbury (State Infirmary), 3; total, 3.

Malaria was reported from: Fort Banks, 1; total, 1.

Meningitis, meningococcal, was reported from: Ayer, 1; Braintree, 1; Brockton, 1; Fall River, 1; Fitchburg, 1; Gloucester, 1; Greenfield, 1; Melrose, 1; New Bedford, 2; Reading, 1; Waltham, 1; Weymouth, 1; total, 13.

Meningitis, other forms, was reported from: Barre, 1; Boston, 3; Brookline, 1; Easton, 1; Fitchburg, 1; Grafton, 1; Marshfield, 1; North Reading, 1; Springfield, 1; Sturbridge, 1; Worcester, 1; total, 13.

Paratyphoid infections were reported from: Boston, 1; Gardner, 2; Quincy, 1; total, 4.

Pellagra was reported from: Boston, 1; total, 1.

Septic sore throat was reported from: Amesbury, 1; Boston, 3; Brockton, 2; Cambridge, 1; Chelmsford, 1; Georgetown, 1; Greenfield, 1; Ipswich, 1; Malden, 2; Merrimac, 1; Newton, 1; Northbridge, 1; Salem, 1; Winchendon, 2; total, 19.

Typhoid fever was reported from: Boston, 3; Lowell, 1; Stoughton, 1; Worcester, 1; total, 6.

Undulant fever was reported from: Ashburnham, 1; Brookfield, 1; Lee, 1; Millbury, 1; Weymouth, 1; total, 5.

Mumps, after showing record-high incidence for the past seven consecutive months, is still at a high level.

Chicken pox, meningococcal meningitis, German measles, poliomyelitis, paratyphoid, scarlet fever, pulmonary tuberculosis and undulant fever were reported at figures above their five-year averages.

Bacillary dysentery, measles, lobar pneumonia, other forms of tuberculosis and whooping cough were reported at figures below their five-year averages.

The focus of animal rabies previously noted in the northeastern section of the State is still active in Middlesex County. Cases were reported from Tewksbury, Lowell and Woburn.

## NOTES

George R. Cowgill, associate professor of physiological chemistry at Yale University and editor of the *Journal of Nutrition*, was recently awarded the \$1000 Mead Johnson and Company prize by the American Institute of Nutrition for researches dealing with the vitamin B complex. The presentation was made to Professor Cowgill by Dr. Albert G. Hogan, professor of agricultural chemistry at the University of Missouri and president of the Institute, at exercises in The Copley-Plaza, Boston.

Dr. Richard P. Strong, professor emeritus of tropical medicine at Harvard Medical School, recently delivered the fifth series of the John Wyckoff Lectures at New York University College of Medicine. The general title was "Tropical Diseases and the War," and at the first lecture, Dr. Strong discussed dysentery, typhus fever and plague, and at the second, trypanosomiasis and onchocerciasis.

## CORRESPONDENCE

## DIPHThERIA ANTITOXIN

*To the Editor:* The Department of Public Health has been distributing diphtheria antitoxin in packages of 1000, 5000 and 10,000 units. Since present opinion favors the administration of at least 10,000 units to all but the very mildest cases of the disease, the department is discontinuing the distribution of the 5000-unit package. When it is desired that only 5000 units be administered, the appropriate amount may be obtained from a 10,000-unit package.

The elimination of this package will also effect economies in the use of paper and glassware, both of which are becoming increasingly difficult to obtain. Because of this increasing scarcity, the department likewise earnestly requests the co-operation of physicians, hospitals and boards of health in the maintenance of all possible economies in the distribution of biologic products. By ordering only the quantities needed for two to four weeks, and by promptly returning all unnecessary surplus stocks, outdated products and empty containers, the department will be greatly aided both in maintaining an adequate supply of needed materials and in effecting economies in the distribution of biologic products. Materials to be returned should be sent to the Antitoxin and Vaccine Laboratory, 375 South Street, Jamaica Plain, Massachusetts.

PAUL J. JAKMAUH, M.D.  
Commissioner of Public Health

State House  
Boston

## REPORTS OF MEETINGS

## BOSTON ORTHOPEDIC CLUB

A regular meeting of the Boston Orthopedic Club was held at the Boston Medical Library on November 17. Colonel Norman T. Kirk, of Washington, D. C., spoke on "The Evacuation and Emergency Treatment of War Wounded." A tentative plan for the management of wounded in a zone of advance includes an aid station for each battalion, a collecting hospital for these stations, a clearing hospital and an evacuation hospital. The first of these can naturally be employed only when the position of the troops is established, not in advance or retreat. *There should be medical troops with each battalion, and*

minimal medical equipment consists essentially of first aid material. Their function is the carrying of the wounded to the collecting station, at which point the task of the medical regiment ends. Thereafter, it becomes the duty of the army to transport the patients.

The progress through the various stations of a hypothetical patient with a compound fracture of the femur was traced. Since all soldiers now receive three prophylactic injections of tetanus toxoid, the administration of tetanus antitoxin is no longer a problem for the first aid station. The first aid pack that each soldier carries contains 90 gr of sulfanilamide, with instructions for its use in compound fractures. Iodine is used around the wound immediately, and an occlusive dressing is applied. A Thomas splint is applied, but no ankle hitch is employed because of the danger of trauma if a long haul is necessary. Blankets are wrapped in a manner designed to lessen the degree of shock. Morphine is administered either on the litter or at the aid station. Sulfanilamide is given orally in doses of 15 gr every four hours until discontinued at some later post, its later use in the wound itself is a matter of choice at these centers. Sodium amylal which has been demonstrated to decrease the degree of surgical shock, may be employed in the future. It has been estimated that proper splinting diminishes the shock of original transit from 50 to 15 per cent. There is not much specific shock therapy at the aid station, except the use of blankets, for heat, and of the Trendelenburg position.

The collecting station is about 1000 yards behind the aid station, and transportation between these points is accomplished by litter only. It has been shown that to traverse such a distance under war conditions of shell fire requires from one to two hours. At this point, there is also very little protection or specific treatment but some segregation of patients can be carried out.

Transportation from here to the clearing hospital three or four miles away, is accomplished by ambulances and requires an hour or more. Advancing troops always have the right of way on the roads and may seriously hamper the evacuation of wounded. Furthermore, there is no ambulance service by day unless air supremacy is certain and patients may thus be forced to wait over in the meager collecting hospitals for as long as eighteen to twenty-four hours. At the clearing hospital, which consists merely of tents, the cases are divided and allocated to their appropriate places. Here also, the first bit of secondary treatment is carried out, such as the repair of splint, and the renewal of dressings. Plasma or serum is administered to patients in extreme shock. An emergency surgical unit associated with this clearing hospital takes care of urgent abdominal, thoracic and head injuries as well as bleeding cases. Amputations are performed on cases that would otherwise be nontransportable. Unfortunately, no operative case can be transferred for six days which is much too long if a retreat becomes necessary. Airplane ambulances are desirable and feasible, but can be applied only after fighters, bombers and transport ship, have been made available in sufficient numbers. No intricate apparatus is employed to evaluate the shock of a patient but clinical diagnosis is relied on.

The wounded are then taken by the army ambulance corps to an evacuation hospital ten to twenty miles in the rear. It was pointed out that because of the rapid change of battlefield trucks rather than trains may become a necessity for the carrying of supplies for such centers in the rear. Each of these hospitals usually has about 750 beds but as many as 2500 cases may be referred to it

during a twenty-four hour period. Segregation of the more urgent is, therefore again necessary. The hypothetical fractured femur is still on the original litter and fixed in the same Thomas splint. Depending on the severity of the injury and the amount of congestion at the hospital, the fracture may be repaired at this point. For mechanical cleansing, there will undoubtedly not be enough water and saline to carry out the desired technique. Therefore, mechanical cleansing takes the form of cutting away all devitalized tissue and removing foreign bodies and bone fragments. Here, for the first time, dried blood and plasma are available for all. More emphasis is being placed on the thorough treatment of simple wounds at this hospital, with the idea of retaining the soldier in the battle area and thus not losing him for the duration so far as that sector is concerned. These wounds are debrided carefully, dusted with sulfanilamide and primarily sutured. Formerly, many such soldiers would either have succumbed to gas bacillus infection or have been lost to their company. This latter fact was considered bad for the morale.

The further treatment of compound fractures is by the Orr method, which comprises the thorough cleaning and debriding of the wound and the immediate application of plaster after the wound has been packed with an impregnated gauze. It is reported that in the recent Spanish war there was only one death from gas infection in over a thousand cases, and that only eight casts were removed because of sepsis. Dr. Kirk offered the objection that most of the patients with gas bacillus infection would have been dead before arrival at this station. Furthermore, the treatment of fractures by this method affords only mediocre results at best, and is not recommended for fractures of the femur. There is evidence that there may be considerable collections of purulent material in joints and soft tissues despite the absence of fever or pain, and this leads to cachexia and chronic debility. It has been concluded by the French observers, therefore, that such treatment of compound fractures is advisable only for short hauls. On the whole, Dr. Kirk believes that plaster is not effective in the stabilization of fractures of the shafts of long bones. Matthews, of London, does not dare use plaster even for short journeys without splitting the cast or making a window, either of which defeats the purpose of this method. Even its staunchest advocates do not use this technique if there is any soft tissue damage, and insist on twenty-four hours of observation before transportation. Some surgeons strongly advocate the use of sulfanilamide locally, whereas others use only vaseline packs. Dr. Kirk favors the use of 10 gm of sulfanilamide locally, packing of the wound, fixation by a Thomas splint or skeletal traction and the continuance of chemotherapy orally. A wound is considered potentially clean only if it is widely debrided and loosely packed.

Statistics reveal that 30 per cent of all injuries are associated with compound fractures—6 to 8 per cent of an infantry division become casualties in each day's fighting, the proportion of killed to wounded being 1:4. Therefore, the number of casualties daily is 900 to 1000 men for each division.

The discussion was opened by Dr. Elliott C. Cutler, who advocated the blood grouping of all soldiers and their congregation in companies according to such groupings. The expert training of the members of the aid station was highly recommended since this is often the place where the most important dressings are carried out. Time is most vital in abdominal injuries, and in thoracic wounds and head injuries. The last are apparently decreasing with the diminishing use of trucks in actual

warfare. It was warned that many more wounded will of necessity be left in the field with the increasing mobility of war, for they cannot be transported fast or far enough with trucks. The use of plaster, for transportation only, was urged as a means of comfortable and easy removal. It was pointed out that chloroform is an ideal anesthetic for healthy young men: it has a rapid induction and recovery, is of small bulk, and is good in the desert or on ship-board.

Dr. G. W. Taylor stated that intravenous anesthesia may be the answer to that problem, at least partially. He expressed some dissatisfaction with the reported results of the Orr method of treating compound fractures.

Dr. R. C. Cochrane believes that splints give good immobilization, with a minimal amount of shock. Although army regulations are admittedly necessary in the front hospitals, some allowance for variation in technic should be made in the evacuation and general hospitals. Plaster as a means of immobilization for short hauls may be acceptable, but it becomes particularly dangerous for any prolonged period because of the lack of signs and symptoms in the event of sepsis.

Dr. O. J. Hermann read excerpts from letters of Dr. Charles Bradford, in England, which indicate that the Orr method is gaining wide acceptance even among men who saw and used other methods, but that it is not used blindly in every case. For the treatment of shock, strategically placed stations permit rapid delivery of all types of blood. There has been some trouble with the coagulants in plasma. Serum has proved effective, especially in the initial treatment of burns. For anesthesia, nitrous oxide, oxygen and ether and chloroform are still being widely used. Nitrous oxide is good for chest surgery, especially in avoiding complications. Pentothal may supplant some of these for shorter procedures.

In conclusion, Dr. Kirk stated that although chloroform is a good, safe anesthetic in competent hands, there are not enough such trained men. Nitrous oxide, oxygen and ether is being used in Egypt with great success. Plasma has been used extensively at the Walter Reed Hospital, with no reactions. The Roger-Anderson method for the treatment of fractures has fallen into disuse in the army because of the incidence of osteomyelitis and the failure to control the pain adequately. Furthermore, there is not the free motion at the joint that is so widely publicized, for the fixation pushes the surfaces together.

#### UNITED STATES NAVAL HOSPITAL

At a regular meeting at the United States Naval Hospital in Chelsea on January 9, Dr. Francis T. Hunter, recently of the Massachusetts General Hospital and now a member of the Medical Corps of the United States Naval Reserve, spoke on "Transfusions." The discussion was confined to some of the difficulties with and the new developments in the use of blood and its substitutes. Dr. Hunter added that the Army and Navy are now typing the blood of all men in the armed forces and attaching an identification tag with this information to each individual, the Landsteiner method of nomenclature being employed.

Some of the possibilities of blood typing in legal medicine were pointed out. If one parent is Group AB and the other is Group O, all the children will be either Group A or B. Another corollary of this rule is that if either parent is Group AB, there can never be any children with Group O. Infants can be typed immediately after birth, for the agglutinogens of the human cells are present

early in fetal life; however, the agglutinins of the serum may not be detectable for several months or even a year, so that infants may occasionally receive blood of other types without mishap. Subgroups 1 and 2 of Group A are often blamed for reactions and deaths, but there is as yet no good evidence that they are clinically significant. All groups have Subgroups, m, n or mn, which seem to be unimportant for transfusion purposes but may help in medicolegal problems.

Since the agglutinins of serum are destroyed by bacterial contamination, test serums should be discarded after one week. One should also be careful of the cleanliness and the type of glassware, since serum deteriorates in the presence of alkali. If test serum is being made by an institution, care should be taken to titrate the serum before pooling, and only high-titer serums should be employed—otherwise, incompatibilities may not be detected in typings. Lecithin has proved a valuable aid in ruling out pseudoagglutinations due to rouleaux formation. By placing a small amount of this substance, which increases the surface tension of the cells and prevents the formation of biconcave disks on the slide, rouleaux formation is avoided. This occurs primarily in acute infections or in any person with an increased sedimentation rate. If any doubt of the compatibility of donor and recipient of the same type remains after all the usual measures have been tried, 20 cc. of blood from the donor may be injected into the recipient; the rest of the transfusion can be safely given if there is no reaction within twenty minutes.

It is reported that, when all known causes of transfusion reactions have been removed, there are still slight temperature elevations in from 25 to 50 per cent of recipients. But if the blood is taken when the donor is fasting, these slight febrile reactions are reduced to about 3 per cent; furthermore, this results in a much smaller number of other allergic reactions. Reactions from unclean apparatus are now rather a minor consideration. One final warning is for the person taking the blood to make sure that the donor is who he is supposed to be, for such errors have led to lawsuits.

Dr. Hunter then discussed blood banks and blood substitutes. The former are expensive and troublesome, but are of value in communities where there is no supply of readily available donors. Even when refrigerated, whole blood changes with time and especially under conditions that increase the number of enzymes. All these factors favor laking of the erythrocytes, and free hemoglobin in the circulating blood causes changes of the renal tubules that may be fatal—incidentally, these changes are similar to those of arsine gas poisoning, which apparently causes laking of the circulating erythrocytes. Agitation also lakes red blood cells, and this factor has made traveling blood banks for armed forces impracticable. The best blood bank is that provided by the men in service, with type tags attached, in whom the freshness of the blood is ensured.

Plasma will never completely replace whole blood, for erythrocytes are eventually necessary in most cases. It is better than whole blood in burns, because of the hemoco-concentration, but has not proved so beneficial in nephrosis as had been hoped. Liquid plasma obtained from the deteriorating blood of blood banks apparently lasts only about nine months, whereas dried plasma seems to stay unchanged for as long as five years. The latter product is now available on the market for \$26.22 for the equivalent of 250 cc. of liquid plasma, which is equal in osmotic effect to a 500-cc. whole-blood transfusion and is therefore not very expensive. The beef albumin of

Cohn appears very promising, he has already removed the beef antigens and is rapidly finding methods for removing other impurities. This may be a cheap blood substitute and may outmode all others as a temporary expedient. This is another argument against investing large amounts of money in blood banks at the present time.

The following points were brought out by Dr Hunter in the discussion. Although it may be possible to use Group O donors with impunity, in many cases, occasionally in recipients who have had either no previous transfusions or one from another type, it is not wise to give multiple transfusions from a so-called universal donor, for, in certain cases, there may be a temporary heightening of the agglutinin titer and a true and serious reaction of incompatibility. If one must employ this type, it is advisable to take serum for direct matching from the recipient between each transfusion.

The early and unmistakable signs of kidney shutdown from an incompatible transfusion reaction are renal pain, cyanosis, chest pain and dyspnea. These occur almost immediately, and reactions after three or four hours are usually attributable to some foreign protein from the apparatus or donor. Decapsulation for renal failure will probably not prove efficacious, if the experience at the Massachusetts General Hospital is any criterion, for it has been shown that such a kidney puts out less urine than its nondecapsulated mate. Alkalinization of such patients is logical, for hemoglobin is more soluble at a high pH. This will probably not result in the solution of crystalline material, in the kidney tubules, but may prevent the further precipitation of hemoglobin.

## BOOK REVIEWS

*Diseases of the Nails*. By V Pardo-Castello MD. With a foreword by Howard Fox, MD. Second edition. 8°, cloth, 193 pp., with 94 illustrations. Springfield, Illinois: Charles C Thomas, 1941. \$3.50.

The manifestations of disease in the nails are puzzling to most physicians. This book should therefore be a welcome addition to any medical library, whether of the individual physician or of the medical school or hospital.

The text of this edition has been definitely improved. Emphasis has been placed on the numerous general diseases in which nail changes may occur, as well as on affections peculiar to the nails. The histology and pathology are discussed rather briefly, but an excellent feature of the book lies in the many and excellent photographs, which add so much in the assimilation of the text. Attention should be called to two valuable tables—one regarding the occupations with characteristic nail changes and the other listing changes caused by poisons. An extensive bibliography and numerous excellent illustrations add much to the value of this book.

*Teaching Preventive Medicine to Medical Students, with Special Reference to the Use of Health Department Facilities*. By Hugh R Leavell, MD, DPH. 8°, paper, 77 pp., with 9 tables. New York: The Commonwealth Fund, 1941. 25c.

A discussion of the use of health-department facilities for teaching preventive medicine to medical students is timely, since this is one of the more recent suggestions in the field of public health, and one that has already been tried out in many medical schools. The material reported was gathered by the questionnaire method, and has been sifted by an author who is obviously familiar with the difficulties faced by both medical schools and

health departments. It is of particular interest to those concerned with this phase of medical education, and has many tables and comments that may be of interest to others. It is a carefully prepared and worthwhile statement of the subject for 1941, and one hopes that a comparable study in 1951 not only will be made but will show a natural growth of this potentially valuable method of instruction.

*The Therapeutics of Internal Diseases*. Supervising editor: George Blumer, MD. Associate editor: Albert J Sullivan, MD. Three volumes. 8°, cloth. Vol I 872 pp., 136 illustrations, with 26 tables and 1 chart. Vol II 1042 pp., with 2 charts and 14 tables. Vol III 738 pp., 39 illustrations, with 1 chart and 2 tables. New York: D Appleton Century Company, 1941. Sold only as a set, \$40.00.

In these days, when the literature on any detail of medicine has become so voluminous it is impossible for any physician to make inquiry with satisfaction among the many interesting scattered findings and advances in the field of therapeutics. Indeed, the literature increases so rapidly over the field as a whole that one is forced to retreat in blind confusion. To overcome this situation, compilations of what known as reference books are published. Even if a penitential search through a series of reference works consumes time, it remains, so far, the most satisfactory method of obtaining information of various kinds from competent authority. Further elaboration can be pursued from reference literature.

With this in mind, one can consider the worthy enterprise edited by George Blumer. Volume I contains the following splendid sections on 'Nutrition and Dietetics' (A Smith), 'The Principles of Endocrine Therapy' (K W Thompson), 'The Principles of Serum and Vaccine Therapy' (M Eaton), and 'Specific Therapeutic Techniques' (W J Bruckner). Unfortunately, this helpful material is sandwiched among some four hundred pages of questionable therapeutic procedures from spa therapy through a galaxy of peculiar methods of various forms of physical therapy. This section on physical methods is muddled and poorly planned, and merely adds to the confusion already present in physical therapy, emphasizing its lack of physiologic background.

Perhaps the most important and best presented section is in Volume II. The four hundred and fifty-four pages dealing with pharmacology, therapeutics and toxicology, written by Louis S Goodman, stand well above the rest of the sections and form the bulwark for the entire edition. The section on virus diseases (J R Paul, G Klatskin and M E Howard) is a dried extract withdrawn from already present standard reference material and reveals the stigmas of resemblance with some face lifting to other compilations. Thus, this section, which should be of great interest today, reveals none of the remarkable interrelations among virus diseases. In the same volume, the sections on Rickettsiae (Blumer), and more especially the mycobacterioses (E N Packard, H E Hasseltine and W T Longcope), the bacillary infections (J H Musser and P H Jones, Jr), and the coccid infections (M Finland, C S Keefer and E H Place) are superb analyses and dissertations.

Volume III includes a chapter on diseases due to fungi (D T Smith), a remarkably capable section by Faust on metazoan diseases and, no less interesting, a precise chapter by Craig on protozoan diseases. These sections show careful review and study and include material on intoxications (Blumer). The section on diseases of physical

agents is incomplete, and the authors (E. Lawrence and H. Martland) fail to elucidate from a physiologic standpoint the nature and treatment of accidental electrical injuries. Seasickness is not linked up with any of the important work done in Britain on this subject. However, this part of the volume is offset by reliable sections on the treatment of diseases of the lower respiratory tract (D. S. King), the treatment of diseases of the blood and lymph vessels (I. S. Wright), and the treatment of heart disease and heart failure (H. M. Marvin).

On the whole, the three volumes represent the time-consuming editorial efforts of Dr. Blumer, who with great care has attempted to assemble data pertinent to therapeutics; indeed, it is today the best of its kind for its comprehensive scope.

---

*Observations Made during the Epidemic of Measles on the Faroe Islands in the Year 1846.* By Peter L. Panum, M.D. 8°, cloth, 111 pp. New York: published by the Delta Omega Society and distributed by the American Public Health Association, 1940. \$2.50.

In the year 1846, an epidemic of measles in the Faroe Islands offered an exceptional opportunity for the study of the disease. The population was scattered, sparse and virtually nonimmune, since measles had not appeared there for sixty-five years. Moreover, no other eruptive fever was present to confuse the issue. The conditions possessed "the potentialities of a vast experiment." But successful experiments require sharp observations, imagination and an open mind. These Panum had; and the man and the occasion met. The result is one of the classics of epidemiology.

Up to this time, as Dr. Doull points out in his introduction, it was still believed that, although measles was usually spread by direct contact, it might sometimes arise spontaneously, and the notion of a *contagium vivum* as the cause was held by very few. It was supposed that the disease was most readily transmissible in the desquamative stage, and estimations of the incubation period varied widely.

Panum settled the fact once and for all that the exanthem appeared with great regularity thirteen or fourteen days from the effective exposure, which meant that the disease was transmitted "at precisely the time that the exanthem was breaking out or had just broken out." He said nothing of infectivity prior to the eruption, although some of his histories indicated it. He doubted, if he could not prove, that the disease was not transferable in the post-eruptive period. He himself observed no instance of transmission by fomites. He offered, it is true, no explanation of how the infectious material is passed out of the body; indeed, he hazarded no opinion concerning the nature of the morbid agent. Regarding spontaneous origin, he could only say that it did not occur in the Faroe Islands. Nevertheless, his work will stand for all time, and it is most fitting that it should be published in this handy translation.

*The Pharmacology of Anesthetic Drugs: A syllabus for students and clinicians.* By John Adriani, M.D. Second edition. 4°, cloth, 86 pp., with 102 illustrations. Springfield, Illinois: Charles C Thomas, 1941. \$3.50.

There has always been a real need for a book of this type, which correlates clinical anesthesia with the pharmacology and physiology of the drugs in current use, for both the clinician and the medical student. Indeed, it is a book well worth reading to refresh one's mind on the

action of the lethal drugs used outside the field of anesthesia.

The author has accumulated his data from numerous observations and personal experiments. The material is presented in an honest, scientific manner, with the thought that the facts presented might serve as a guide until further investigation may be obtained. The subject matter is uniquely arranged in diagrammatic fashion, to focus attention on the physiologic and pharmacologic changes occurring with the various organs and systems of the human body, so that further study and interest in the fundamental sciences associated with anesthesiology may be stimulated.

The subjects covered include general properties and chemical natures of anesthetic drugs, general systemic effects on the respiratory, circulatory and central nervous systems, and disturbances of respiration including oxygen and carbon dioxide transport, oxygen want and the physiologic and toxic effects of carbon dioxide.

The various anesthetics include gaseous agents (nitrous oxide, ethylene and cyclopropane), volatile agents (ethyl ether, divinyl oxide, chloroform and ethyl chloride), non-volatile agents (bromethanol with amylene hydrate [Avertin], trichlorethanol and paraldehyde), barbiturates, local anesthetics and opiates. The nonanesthetic drugs used in conjunction with anesthesia are also discussed. In the last chapter, some clinical considerations are presented, such as preanesthetic medication, technics of administration, carbon dioxide absorption, complications and accidents, anesthetic and respiratory complications, and the explosibility of anesthetics. There is also a brief bibliography, which covers more recent contributions to this field of medicine.

---

*Clinical and Experimental Investigations on the Genital Functions and Their Hormonal Regulation.* By Bernhard Zondek. 8°, cloth, 264 pp., with 59 illustrations and 44 tables. Baltimore: Williams and Wilkins Company, 1941. \$4.50.

Many of the advances in knowledge of the sex hormones are associated with the name of Zondek. The author includes in this short monograph a résumé of his lifework with sex hormonology, as well as a review of the work by other investigators that corroborates his findings. This volume is of monumental scope, and bears witness to his intense pursuit of facts. Typical of the pure scientist are his experiments with water from the Dead Sea. All layers of the sea were analyzed, and it was found that the water and sludge at the bottom contain large amounts of estrogenic substances, whereas other layers have little or none.

The chapter entitled "Fate of Sex Hormones in the Organism" shows that naturally occurring estrogens are rapidly destroyed in the body, whereas synthetic estrogens (Stilbestrol) are very slowly destroyed. This accounts, perhaps, for the powerful and often toxic action of the latter. Evidence is presented to show that the corpus luteum hormone can produce bleeding of the uterine mucosa alone, whereas it had been supposed that this was possible only in a mucosa previously prepared by the action of estrone. On the basis of present knowledge, an interesting and plausible theory for the menstrual cycle is advanced.

Many of the facts presented in this volume will form the basis of future clinical experiments. The book makes interesting reading for both the practitioner and the investigator, because the author deals throughout with clinical and animal experiments.

## THE RELATION OF TANNIC ACID TO THE LIVER NECROSIS OCCURRING IN BURNS\*

DONALD B. WELLS, M.D.,† HENRY D. HUMPHREY, M.D.,‡ AND JAMES J. COLL, M.D.‡

HARTFORD, CONNECTICUT

THE phenomena associated with severe burns follow each other in a more or less orderly and well-defined chronologic sequence.<sup>1</sup> Death may result almost immediately from overwhelming trauma. Most burned patients are seen in primary reflex shock, a state of marked vascular vasodilatation caused by fright and pain. Primary reflex shock may blend rapidly and almost imperceptibly with so-called "secondary shock," which, with its increasing capillary permeability and massive fluid shift or loss, may be fatal within forty-eight hours. What we are accustomed to calling "toxemia" ensues; however, the use of the adjective "toxic" to describe a patient in poor condition from undetermined causes is certainly no proof that a toxin exists, and belief in a "toxemia" in burns may well arise from the clinician's bewilderment in the face of potent factors that he cannot readily catalogue. It is interesting that no less than twenty substances purporting to be the "burn toxin" have been listed<sup>2</sup> but no specific histopathology for burns has ever been described. Infection is usually a comparatively late stage in the chronologic sequence; but in three or four days, if severe sepsis develops, it may overshadow the whole clinical picture.

Ten consecutive autopsies recently performed in cases of death from burns at the Hartford Hospital serve to illustrate this sequence of events. Two of these patients died from direct trauma within two to four hours after injury; another died of shock or fluid imbalance eleven hours after the injury; 4 more died of "toxemia" ninety-three to one hundred and twenty hours following the injury; another, admitted late, died of infection one hundred and twenty hours after the injury, a blood

culture on admission showing hemolytic streptococci; the last 2 died of complications, 1 fifty-five hours after the accident from the result of an associated cerebral laceration sustained in an airplane crash, and 1 of a cerebral glioma thirty-three days after admission—the glioma was probably the cause of the convulsive seizure during which this patient was burned. The 4 patients who died of "toxemia" are of particular interest, and their cases are briefly presented below because each one exhibited central lobular liver necrosis as an outstanding lesion or as the sole cause of death. Treatment of these patients followed the general principles laid down by one of us<sup>3</sup>: the employment of a tannic acid tub in which a careful débridement was done without an anesthetic, a thin, sterile tan being secured in every case; the tan was subsequently maintained by the use of a tannic acid spray, and for the most part was kept perfectly dry by a current of warm air from a commercial hair drier; intravenous glucose in physiologic saline solution was given in adequate quantities; each patient received whole-blood transfusions; and intranasal oxygen was employed.

### CASE REPORTS

CASE 1. R. W. (H. H. 338,316), a 17-year-old boy, was admitted on July 1, 1937. Practically all his clothing had been burned off when a can of gasoline he was holding became ignited from a bystander's cigarette. The burns were estimated to involve not less than five sixths of the entire body surface. The patient was immediately put in a tub of tannic acid solution, the loose skin removed, and the hair shaved. He remained in the tub 4½ hours and, after being transferred to bed, was sprayed repeatedly with a tannic acid solution and immediately dried with a commercial hair drier. Intravenous glucose and three whole-blood transfusions were given. Continuous intranasal oxygen was started 18 hours after admission. The patient was spontaneously responsive during most of his stay in the hospital, but became increasingly restless and irrational after the 63rd hour, when the blood nonprotein nitrogen was 128 mg. per 100 cc. and the hemoglobin 111 per cent. Death occurred 91 hours after admission.

\*Presented at the annual meeting of the New England Surgical Society, Hanover, New Hampshire, September 5, 1941.

†From the Department of Surgery and the Department of Pathology, Hartford Hospital.

‡Visiting surgeon, Hartford Hospital.

§Resident intern in pathology, Hartford Hospital, assistant in pathology, Yale University School of Medicine.

*Autopsy.* The body was that of a well-developed and well-nourished boy. At least five sixths of the body surface was covered with a firm, dry tan without evidence of infection. There was marked congestion of the viscera, with scattered petechiae, and blood-tinged fluid was present in the body cavities. There was no ulceration of the duodenal mucosa. The liver weighed 1960 gm. and showed no gross changes. The gall bladder and bile ducts were not unusual.

On microscopic examination, all organs except the liver showed nothing but cloudy swelling and congestion. In the central two thirds of the liver lobule, the parenchymal cells showed a granular, deep-pink-staining cytoplasm in contrast to the relatively normal cells in the peripheral area. Throughout this central zone, the nuclei were slightly enlarged, and there were numerous necrotic foci (Plate 1, *A*). A moderate number of mitoses were present in the peripheral zone (Plate 1, *B*). The sinusoids were distended with blood. There was no leukocytic infiltration.

*Comment.* This case showed a combination of early liver necrosis and vascular failure. The latter was probably the greater lethal factor.

CASE 2. N. N. (H. H. 357,822), a 23-year-old man, was admitted on August 18, 1938. An electric flash in a transformer room had ignited his clothing. The entire head, the torso to the waistline, both upper extremities and wide patches on both thighs, both anteriorly and posteriorly, were burned. The patient was put in a tub of tannic acid solution and carefully and thoroughly débrided. He remained in the tub  $2\frac{3}{4}$  hours. This treatment was followed by repeated spraying with a tannic acid solution, which was immediately dried with a commercial hair drier. Three transfusions were given, and no gross fluid imbalance was clinically apparent until the last 24 hours of life, when edema of the lower extremities developed. About 2 hours before death, the patient became restless, complained of severe pain in the upper abdomen, and vomited several times. He died 96 hours after admission.

*Autopsy.* The body was that of a well-developed and moderately overnourished young man. The burned areas were covered by a firm, dry, noninfected tan. The tissues were moist and moderately icteric. A moderate amount (200 cc.) of slightly bloody fluid was present in the body cavities. The viscera showed moderate congestion, with scattered petechiae. The liver weighed 2000 gm., and the cut surface showed a fine mottling, with hemorrhagic points. The gall bladder and biliary ducts were not unusual. No ulceration of the duodenal mucosa was found.

On microscopic examination, except for multiple small thrombi in the lungs and congestion and cloudy swelling of other viscera, significant histologic changes were limited to the liver. The central three fourths of the liver lobules showed extensive hemorrhagic necrosis, with complete disruption of the cords of liver cells (Plate 1, *C*). A few cells in the peripheral region were still intact, and some of these were in mitotic division. A slight diffuse infiltration of polymorphonuclear leukocytes was present throughout, together with a scattering of fat globules. There was no increase in fibrous tissue.

*Comment.* Although the changes present in this case suggested vascular failure, the picture was dominated by the liver necrosis.

CASE 3. K. W. (H. H. 388,162), a 23-year-old man, was admitted on April 26, 1940. An explosion of illuminating gas had resulted in burns involving the entire face and neck, upper chest, back and both arms except for the

palms of the hands. The patient was immediately put in a tub of tannic acid solution, where a thorough débridement was carried out. He remained in the tub for  $2\frac{1}{4}$  hours. After being removed, he was repeatedly sprayed with a tannic acid solution and immediately dried with a commercial hair drier. Intravenous glucose and two whole-blood transfusions were given. For the first 72 hours, the general condition remained satisfactory, and the patient sat up in a chair for several brief periods. Sixty-four hours after admission, the blood chlorides were 428 mg., and the serum protein 6.7 gm. per 100 cc. Eighty-four hours after admission, there was clinical jaundice; the red-cell count was 4,900,000, with a hemoglobin of 104 per cent (16 gm.), the chlorides 425 mg. per 100 cc., the carbon dioxide combining power 56 vol. per cent, the serum van den Bergh (positive, direct) 23 units (115 mg. bilirubin per liter), and the serum protein 6.8 gm. per 100 cc. No clinical improvement was observed after the repeated use of Eschatin. The patient became increasingly stuporous, with a rising temperature and pulse. The urinary output was satisfactory throughout his course in the hospital. Death occurred 110 hours after admission.

*Autopsy.* The body was that of a well-developed and well-nourished young man. The burned areas showed a firm, dry tan without evidence of infection. All the tissues were moist and moderately icteric, and the body cavities contained a small quantity of bile-tinged fluid. The lungs were not remarkable except for slight edema and congestion. The heart, gastrointestinal tract, spleen, pancreas, adrenal glands and kidneys showed no gross anatomic changes. There was no ulceration of the duodenal mucosa. The liver weighed 1240 gm., and was soft and flabby. The cut surface revealed a finely mottled red-and-yellow appearance. There was dark thick concentrated bile in a small thin-walled gall bladder. The bile ducts were not remarkable and contained thin, clear bile.

Microscopic examination showed no histologic changes in any of the organs except the liver. There was extensive central hemorrhagic necrosis involving more than three quarters of the liver lobule, with disruption of the liver cords. Only a narrow zone of intact cells remained in the peripheral areas. These cells varied markedly in size and staining reaction. Many had large nuclei, with irregularly clumped chromatin. Mitotic figures were present, some of which were bizarre forms with scattered chromosomes. Definite evidence of regeneration was not demonstrated. Fat globules were present in slight degree through the area of necrosis and in the remaining liver cells. A moderate number of polymorphonuclear leukocytes infiltrated the interstitial tissue.

*Comment.* In this case, death was due solely to liver necrosis.

CASE 4. W. L. (H. H. 396,523), a 26-year-old man, was admitted on September 18, 1940. While the patient was working under his own car, a pan of gasoline caught fire and the flames spread to his clothing. He walked to the hospital. Diffuse burns involved the left side of the face, neck, chest, whole left upper extremity and the fingers of the right hand. The patient was put immediately in a tub of tannic acid solution and débrided. He remained in the tub  $4\frac{1}{2}$  hours. This treatment was followed by repeated spraying with tannic acid solution, which was immediately dried with a commercial hair drier. Intravenous glucose and two whole-blood transfusions were given. Fifteen hours after admission, the red-cell count was 5,060,000, with a hemoglobin of 97 per cent (15.0 gm.). Sixty-eight hours after admission, there was clinical jaundice, with an icteric index of 53. Ninety-one hours

PLATE 1. Human Liver Lesions Following the Administration of Tannic Acid for the Treatment of Burns.

A. Case 1. Early central necrosis (hematoxylin and eosin  $\times 100$ ).

C. Case 2. Advanced hemorrhagic central necrosis (hematoxylin and eosin:  $\times 85$ ).

B. Case 1. Higher magnification of A, showing mitoses and other nuclear changes (hematoxylin and eosin:  $\times 420$ ).

D. Dr. Helsen's case. Intermediate central necrosis (hematoxylin and eosin:  $\times 85$ ).

after admission, with a normal temperature but rising pulse, the nonprotein nitrogen was 80 mg. per 100 cc., the blood chloride 406 mg., the carbon dioxide combining power 54 vol. per cent, the serum protein 6.4 gm. per 100 cc., and the icteric index 100. The patient died 121 hours after admission.

**Autopsy.** The body was that of a well-nourished and well-developed young man presenting diffuse, satisfactorily tanned burns. There were slight generalized edema and moderate jaundice. The pericardial cavity was entirely obliterated by dense adhesions. The heart weighed 500 gm. Each pleural cavity contained about 200 cc. of bloody fluid. Each lung showed slight edema, and in the lateral portion of the left lower lobe, there was an area of pneumonic consolidation about 10 cm. in diameter. The peritoneal cavity contained 300 cc. of yellow fluid. There were hemorrhagic areas throughout the intestinal tract, but no ulceration. The liver weighed 2390 gm. There were multiple areas of subcapsular hemorrhage. The cut surface was a pale yellow brown, with small hemorrhagic areas throughout. The gall bladder and bile ducts were not remarkable.

On microscopic examination, the pulmonary areas of consolidation showed a characteristic pneumonic picture. The kidney tubules showed cloudy swelling. Almost the entire liver lobule was involved in hemorrhagic necrosis. Only in small foci in the periportal areas were intact cells present, and mitoses were infrequent. Slight diffuse leukocytic infiltration was present. Fat globules in moderate amount were noted in both necrotic and viable tissue. There was very little evidence of bile stasis.

**Comment.** The liver necrosis, which was the most massive of all the cases, was complicated by lobular pneumonia, inactive rheumatic heart disease and vascular failure.

Another case was brought to our attention by Dr. Milton Helpert, assistant medical examiner of New York City. A thirteen-month-old boy was severely scalded over the face, trunk and extremities. The local treatment was tannic acid and silver nitrate. The patient died eighty-two hours after the burn was sustained. The following description of the liver is quoted through the courtesy of the New York Hospital and the Department of Pathology, Cornell University Medical College (N. Y. H. 246,442, Necropsy 9780):

**Gross.** The liver weighs 340 gm. The organ is of normal shape; it is firm but shows a moderate yellow discoloration. The central parts of the lobules are red.

**Microscopic.** In the central half of the lobule, the liver cells are more pale-staining than in the peripheral half [Plate 1, D]. The nuclei of many liver cells are pyknotic, and some cells contain no nuclei. Some of the liver cells are eosinophilic. The liver cells in the peripheral half contain many fat vacuoles but are otherwise normal.

Until a few years ago, it could be truthfully stated that there are no internal or visceral lesions pathognomonic of burns and scalds.<sup>4</sup> Only recently has a specific histopathologic lesion in the liver been reported following certain severe burns. This lesion is so striking that, had it been present in earlier cases, it could not possibly have been overlooked by the army of clinical and experi-

mental observers who have studied burns. In 1938, Wilson, Macgregor and Stewart<sup>5</sup> first described the appearance of the liver as follows:

On naked eye examination, the liver was slightly enlarged, light yellow, soft, greasy and friable. On the cut surface, the lobular marking was conspicuous owing

FIGURE 1. Diagrammatic Summary of Data in Case 5.

to greater pallor of the central zone; sometimes, however, haemorrhage in the central zones produced an appearance resembling "nutmeg" liver. On microscopic examination, necrosis of varying degree of the cells of the central parts of the lobules was seen. In the most extreme examples only a narrow strip of liver substance surrounding each portal tract showed surviving liver cells; the remainder were completely necrotic.

Similar cases at necropsy have been reported by Belt,<sup>6</sup> McClure,<sup>7</sup> Buis and Hartman<sup>8</sup> and others. This striking liver lesion has heretofore been attributed to toxemia or anoxia.

Furthermore, we have seen, and others have reported, human beings with burns treated with tannic acid who have shown definite clinical and chemical evidence of liver damage but have recovered. The following case is typical:

**CASE 5.** R. G. S. (H. H. 407,654), a 15-year-old boy, was stamping out a smoldering tree stump when it burst into flame and ignited his clothing. Burns involved both upper extremities, the left chest and axilla and the right lower extremity. Within 24 hours, there was evidence of liver damage, as indicated by the van den Bergh test and by the prothrombin time, which reached a maximum in 72 hours and then subsided (Fig. 1); the boy recovered, and was discharged from the hospital on the 18th day.

PLATE 2. *Experimental Liver Lesions in Rats Following the Administration of Tannic Acid.*

- A. Experiment 15 (Rat 6). Moderate central necrosis after 0.1 mg. tannic acid (hematoxylin and eosin  $\times 100$ ).  
 B. Experiment 15 (Rat 6). Higher magnification of A, showing mitoses and other nuclear changes (hematoxylin and eosin:  $\times 880$ ).  
 C. Experiment 17 (Rat 4). Moderate central necrosis after 0.2 mg. tannic acid (hematoxylin and eosin:  $\times 75$ ).  
 D. Experiment 17 (Rat 1). Advanced central necrosis after 0.2 mg. tannic acid (hematoxylin and eosin:  $\times 95$ ).

On review of the reported cases and particularly the proved cases coming to necropsy, the common denominator appeared to be that tannic acid had been employed in the treatment. Because it seemed to be of interest to investigate the possible role of tannic acid in the production of liver damage, a series of experiments was planned

tion sites employed. All other organs examined presented a normal appearance except for a slight cloudy swelling. No significant variation in the findings between the rats on either of the specified diets was observed.

The liver damage produced by these injections of tannic acid solution was characterized by: ne-

to determine the effect of subcutaneous injections of tannic acid on the liver in rats.

Albino rats weighing 70 to 90 gm. were selected. They were maintained on specified diets—one group on a house diet of raw bacon, lettuce, bread and grain, and the other on a standard diet of casein, sucrose, salts, cottonseed oil, cod-liver oil and brewers' yeast—for a week or more before being used, as well as throughout the period of experimental observation. Tannic acid (Mallinckrodt, U.S.P., fluffy) was employed. Subcutaneous injections of a 5 or 10 per cent solution of tannic acid were given in doses that did not exceed 1.5 cc. at any one site, to avoid leakage and to facilitate absorption. No anesthesia was used. Rats that survived were killed on the third or fourth day by a blow on the head. The tissues were fixed by formalin or Zenker's fluid, and suitable sections were stained with hematoxylin and eosin.

The rats were injected, usually in groups of 6, with varying amounts (0.05 to 0.40 gm.) of tannic acid in from one to eight sites over a period of forty-eight hours (Table 1). Of the 77 rats injected, 8 failed to survive. Every one of the remainder showed some degree of liver damage, which, in general, varied directly with the amount of tannic acid injected and the number of injec-

tion sites employed. All other organs examined presented a normal appearance except for a slight cloudy swelling. No significant variation in the findings between the rats on either of the specified diets was observed.

The liver damage produced by these injections of tannic acid solution was characterized by: ne-

DISCUSSION

The patients in the cases presented above died largely or solely as the result of a central liver necrosis. Such a necrosis has been observed, in our own cases and in those reported by others, only when the patient has been treated with tannic acid.

The sequence of possible lethal factors in burns treated with tannic acid is shown in Figure 2.

Other workers have burned experimental animals,<sup>8</sup> treated them with tannic acid jelly and produced a central liver necrosis comparable to that observed at autopsy in human beings who had

been treated with tannic acid. In our experiments, a series of rats was subcutaneously injected with chemically pure tannic acid and a central liver necrosis, comparable to that seen in the human patients, was produced. In these experiments, the degree of liver damage was in direct proportion to the amount of tannic acid injected subcutaneously. Similar results have been obtained after in-

FIGURE 2. Sequence of Lethal Factors in Burns Treated with Tannic Acid (Adapted from Gunn and Hillsman<sup>1</sup>).

- A. Reflex shock from fright and pain.
- B. Secondary shock or peripheral vascular failure due to increased capillary permeability and fluid loss or shift.
- C. Bacterial contamination, which may become active infection in thirty-six to forty-eight hours.
- D. Tannic acid poisoning, clinically demonstrable after thirty-six hours and fatal, owing to specific hepatitis, in ninety hours or more; the shift from vertical to horizontal crosshatching indicates the trend of increasing liver damage.

jection of rabbits and guinea pigs with tannic acid. No factor other than tannic acid has entered into the production of liver damage in these experiments.

### CONCLUSIONS

In patients with severe burns treated with a tannic acid solution, tannic acid jelly or tannic acid and silver nitrate solutions, tannic acid poisoning resulting in a hepatitis may become clinically and chemically demonstrable within thirty-six hours and may result in death from a specific central necrosis of the liver in from eighty to one hundred and thirty hours or more.

The specific central necrosis of the liver due to tannic acid poisoning should be distinguished from the cause or causes of the so-called "toxemias" of burns and scalds.

### DISCUSSION

DR. W. IRVING CLARK (Worcester, Massachusetts): I doubt if many of us here have followed the effect of tannic acid treatment in cases of fatal burns through to the conclusion of examination of the liver.

To me, the whole matter is extremely new, and I probably have not been following the literature, although I believe, from talking to Dr. Wells, that the literature is not very profuse on this subject.

It is interesting to follow the exact course of argument in this paper. In the first place, the statement is made definitely that there has been no pathological examination showing necrosis of the liver in cases of burns prior to the use of tannic acid; secondly, this is corroborated by finding necrosis of the liver in the cases presented; thirdly, animal experimentation has been carried out in which animals have been burned, subjected to tannic acid treatment and, then, autopsied, with the finding of central liver necrosis; and fourthly, animal experimentation by tannic acid alone has presented liver necrosis.

The cause of this necrosis is unknown. There has been much discussion about toxemia, which has generally been accepted by most authors. One finds in the literature that the toxemia of burns is a recognized condition, but whether it is due to histamine or to some other substance has never been definitely proved.

The interesting points that I should like to bring out are that chloroform produces a somewhat similar picture, and that inhalation of the fumes of chlorinated hydrocarbons causes a very similar necrosis.

In each of these cases, chloroform and the chlorinated hydrocarbons, one finds that the greater the amount of chlorine in the formula, the more definite and more acute the necrosis. For example, with carbon tetrachloride, a long exposure and a considerable amount of fume must be present before necrosis occurs, whereas with the more complicated chlorinated hydrocarbons such as the "pentas" and "hexas," the condition occurs with comparatively slight exposure.

Those two drugs may perhaps give a suggestion of the cause of this central necrosis. It does not seem logical that tannic acid itself should produce it; possibly, it does, but the question is whether the tannic acid may not produce in the body a change in the metabolism in some way by which there is hyperchlorination of the tissues. I think that this is a purely speculative matter, which should be discussed by pathologists in the future; this may be a step toward the solution of the problem.

The question that I suppose we are all asking ourselves is this, Do these experiments suggest that tannic acid as a treatment of burns should be omitted and some other form of treatment employed?

DR. WELLS (closing): The question that one immediately asks is, If tannic acid produces a specific and often fatal hepatitis, should it be abandoned as a local dressing in severe diffuse burns?

The employment of tannic acid is still, in my opinion, the best treatment for the local injury, and I am not quite ready to abandon it. It may result in the death of certain patients who have been burned, but, frankly, I know of no better local dressing at the present time. Operations for cancer of the stomach may result in the death of certain patients, since the mortality from the operation of subtotal or total gastrectomy is not negligible. However, gastric resection is at present the best treatment for carcinoma of the stomach, and in the hope of saving a patient doomed to die unless the growth can be totally extirpated, both patient and surgeon must accept the risk. A consideration of the mortality in more than 700 burns

treated at the Hartford Hospital during the last twenty-five years shows that since tannic acid was introduced the gross mortality has been cut in half. This is not by any means entirely due to the employment of tannic acid —

I am sure of that. Many factors have entered into the improvement of the records, but I am satisfied that tannic acid has helped to reduce the morbidity and mortality of burns.

## PRESIDENTIAL ADDRESS\*

JAMES B. WOODMAN, M.D.†

FRANKLIN, NEW HAMPSHIRE

MY father, who was a physician in a small town in central New Hampshire, once told me that, when the way seemed dark and I might be blamed for what was not my fault, I should remember that there would also be times when I would be praised and honored more than I deserved.

The latter part of this admonition comes to my mind in the present situation. And I consequently wish to express my heartfelt appreciation for the high honor of being the president of this society, and to tell you that I have for the past year been inwardly basking in the warming sunshine of your favor.

This evening, it seems not inappropriate to present to you briefly four of the names that have made New Hampshire medical history, and the history of the Dartmouth Medical School, noteworthy.

In presenting Drs. Twitchell, Mussey, Crosby and Peaslee, may I remind you that the whole state of New Hampshire contains fewer souls than the city of Boston alone, and that in the period of which I speak we were largely a farming population, widely scattered, with no hospitals and no centers, in the modern sense, for medical research? There were no modern laboratories, no electricity, no trains, no automobiles, no telephones, no good roads and, worst of all, no asepsis and, until near the end of the period, no anesthetics. Can you not see these gentlemen starting out for a distant village or farm, in their clothes of a former generation, on horseback, or in their two-wheeled chaises, toiling over the sandy, snow-bound or muddy roads? And before them and after them, one generation after another, struggling toward the light.

These four great men and great surgeons, country doctors and pioneers of their line, were all New Hampshire men. They were educated at Dartmouth College. They worked and taught at the Dartmouth Medical School. They passed on the knowledge they acquired to future gen-

erations. They were all a part of the New Hampshire medical tradition of which we are so proud.

Amos Twitchell was born in Dublin on April 11, 1781, on the slopes of old Mt. Monadnock, and it was said of him that he was as grand and honest as the old mountain itself. He possessed initiative, and was of the type of pioneer surgeons who have done so much the world over to make our present-day work possible. He was a poor farm boy, entirely lacking in this world's goods but blessed with an ambition that is a greater endowment. He prepared for college at New Ipswich Academy, entered Dartmouth at the age of seventeen, received his degree in 1802, and immediately began the study of medicine under Dr. Nathan Smith. He became a very proficient anatomist and in due time became assistant to Dr. Smith and was thus associated with him for some time at the medical school. He then practiced for short periods in Norwich, Vermont, and Marlboro, New Hampshire.

While in Marlboro, he encountered the case that brought him prominence at the time, and fame ever since. In October, 1807, John Taggart, of Sharon, had been shot in the neck while attending some military maneuvers. His jaw was shattered, all adjacent parts were severely bruised, and extensive mortification had set in. On the tenth day, while dressing the wound, Dr. Twitchell remarked that the common carotid artery was bare and appeared to be sloughed on its surface. While he was leaving the house, a terrific hemorrhage started, the blood spurting, as he says in his account of the case, a distance of three or four feet. He swiftly removed the dressings and placed his thumb over the bleeding point, and with only the help of the boy's mother, he cut down on the artery and finally succeeded in working around it by blunt dissection and getting a ligature on it. This was followed by some oozing, and as soon as pressure was removed, by some spurting. The lad was by this time unconscious and his condition was precarious, so that no further attempt at ligation was attempted. The bleeding point was then compressed by a small piece of dry sponge,

\*Presented at the annual meeting of the New England Surgical Society, Hanover, New Hampshire, September 5, 1941.

†Member of staff, Franklin Hospital, Franklin, New Hampshire.

covered by larger pieces to a depth of two or three inches, and this inverted cone was held down by bandages about the head and neck for pressure. The patient recovered. This operation was original, so far as Dr Twitchell was concerned although it had been performed by Fleming, an English surgeon, in 1803, it was not reported until 1817.

Dr Twitchell did all the major operations of the day, and did them repeatedly. In one year, he performed three tracheotomies for the removal of foreign bodies, and all were successful. Can you visualize him doing this emergency operation on a small infant's short, fat neck and without an anesthetic? He frequently operated for stone in the bladder. In 1838, he removed the arm, scapula and part of the clavicle for an enormous osteoma; this was the third time such an operation had been done, each previous one having been performed by a New Hampshire surgeon. He trephined the tibia for abscess, did excisions of the joints and had performed ovariectomies before it was known that McDowell had done the operation.

Dr Twitchell was a fine Christian, a genial gentleman and a tireless worker; he was extremely temperate and inclined to be a vegetarian. He was three times president of the New Hampshire Medical Society and always took an active part in the meetings, giving much attention to the eradication of quacks and charlatans, with which the state seemed to be afflicted at this time.

He was offered professorships at Dartmouth Medical School, Castleton and Vermont University but was unable to accept, partly from financial considerations and partly on account of his health. In his correspondence, I find a letter to the president of Dartmouth College in which he expressed the hope that the stipend might be raised to \$1200 per annum, that he might not be obliged to sustain too great a financial loss.

Reuben Dimond Mussey was born in Pelham on June 23, 1780. He was the son of Dr John Mussey, who bore a good reputation as a physician in his locality. There was not much money available in the family, but after district school he managed to attend the academy at Amherst. He was then obliged to earn enough for his further education by working on a farm and teaching school. His father had been able to teach him Latin, which was a prerequisite in those days. He must have worked to good advantage, for at the age of twenty-one he entered the junior class at Dartmouth College. He continued to teach during vacations, and he graduated from college in 1803 and immediately became a pupil of Dr Nathan Smith. At the end of this course, he sustained a public examination, and read and de-

fended a thesis on dysentery; the degree of B.M. was conferred on him in 1805. In 1812, he received his M.D. from the University of Pennsylvania School of Medicine. He was then called back to Hanover, where he was a professor in the medical college from 1814 to 1838. He then taught at Bowdoin for four years, later, he was professor of surgery at the University of Cincinnati College of Medicine for fourteen years and at Miami Medical College, which he founded, for five years.

As a surgeon, he enjoyed a reputation second to none in the state.

So-called brilliant surgery he regarded with contempt. He cared not to make a figure but to benefit his patient, not to gain eclat, but to save human life. He believed much in skilled surgery, something in nature, but most of all in God. Frequently on the eve of a great operation he knelt at the bedside and sought skill and strength and success from the great source of all vitality.

Doubtless, the confidence and sense of peace following this must have been of great advantage to both surgeon and patient at the operation. I think you will all agree with me that we have a dread of operating on one who lacks this confidence.

Mussey's famous discussion with Sir Astley Cooper over the healing of intracapsular fractures is well known and gave him, at the time, much prominence, since it was somewhat unusual, as he remarked, to win an argument with "one who was always positive, and sometimes right."

Dr Mussey is said to have been very skillful with his hands and to have handled the knife precisely and cleanly, a quality conducive to good healing in his day as in ours. Evidence of his dexterity is a clock still in the possession of his descendants; he made this when a young man. While in college, he also made his own shoes.

The case that brought him the greatest fame was probably that in which he successfully ligated both carotid arteries. He did this operation for Mr Jason Pettee, a resident of Hanover, and the operation was performed for a bleeding nevus of the vertex of the head, which threatened a speedy death. He tied one carotid, and twelve days later he tied the other. A few weeks later, he successfully removed the tumor. This was the first recorded case in which both carotids were successfully tied. Naturally enough, the operation gave him a reputation all over the surgical world.

He removed a boy's tongue, which measured eight inches in circumference and projected five inches beyond the jaws, and the patient recovered. At one operation, he removed the scapula and a large part of the clavicle from a patient for whom he had previously amputated at the shoulder joint. Dr Mussey mistakenly supposed that this

was the first operation of the kind in the history of surgery. As a matter of fact, it was first done by Dr. Dixi Crosby in 1836, and then by Dr. Mussey in 1837 and by Dr. Twitchell in 1838—all New Hampshire surgeons. Dr. Mussey several times removed the upper and portions of the lower jaw. His records show that he did lithotomies in 49 cases; all but 4 patients recovered. He repaired strangulated hernias in 40 cases, with only 8 deaths. He treated 45 cases of varicocele successfully. He operated for perineal fistula in 4 cases and for impermeable stricture of the urethra in 2, and did a large number of plastic operations, with fine results. He also successfully treated a rectovaginal fistula. These are only a few samples of the enormous amount of work he was constantly carrying on.

Dr. Mussey was a small man with a high forehead, high cheek bones, a thin face and square chin. He had a brusque, rather forbidding manner. His Puritan ancestry gave him none of the sparkle that we now speak of as personality. He won his reputation purely on merit. His motto was, "Do well and wait." As a young man, he was dyspeptic and developed the habit of living on a strictly vegetable diet, and this rule was followed more or less all his life. He was a very religious man and very abstemious. Many of his speeches and pamphlets were directed against the use of alcohol and tobacco. At one time during his later life, his physician prescribed some stimulant. He finally consented to take some brandy in eight-drop doses, from which he said he could feel quite a strong effect. In those days, when liquor was so universally and so freely used, he must have felt that he had won his argument for temperance, for in spite of his dyspepsia he lived to the ripe age of eighty-six.

Dr. Mussey's sons, grandsons, great-grandsons and so on, without a break in the line, were physicians down to the seventh generation, which is represented, I am informed, at the present time by a young man who is a student at Dartmouth Medical School.

Dixi Crosby was born at Sandwich on February 9, 1800, shortly after his father, Dr. Asa Crosby, had been ordered out of Moultonboro by the sheriff for fear that he might become a financial burden on the town, on account of his poor health. Dr. Asa had ten sons, several of whom became physicians. Prior to Dixi's birth, there naturally had been much speculation about whether this child, too, would be a boy. Dr. Asa had favored another son, and when the youngster arrived on the scene and it was ascertained that it was a boy, the exulting father exclaimed "*Dixi*," or "I told you so." And Dixi he remained.

Up to his nineteenth year, young Crosby had not been much interested in books and had made an early venture into business. This however, was not a success, and he finally returned home to Gilmanton, where the family then resided. He studied with his father, a method of gaining knowledge and experience prevalent in those days, and one that, it seems to me, has much to recommend it. He also attended Gilmanton Academy and later went to Dartmouth College. He was a keen student of anatomy, and one of his biographers has a good deal to say regarding certain difficulties in which he found himself over the procuring of anatomic material, which at that time was extremely difficult to obtain.

After receiving his degree from Dartmouth Medical School, he practiced for ten years in Gilmanton and for three years in Laconia, then known as Meredith Bridge. He had by that time established a fine reputation as a surgeon, and in 1838 he was called to take the chair of surgery and obstetrics at Dartmouth by Dr. Mussey, who was retiring. He held this position for thirty-two years.

His brother, Nathan, in his book, *A Crosby Family*, tells of Dixi's first major operation. It was done while Dixi was in his first year of medical study. He accompanied his father to a consultation in the case of a man whose leg had been frozen, and whose condition was most critical. It was agreed by the physicians that amputation at an earlier stage might have saved the patient's life, but that it was now too late to attempt it. Young Crosby urged that the operation still be performed. The elders shook their heads. He even proposed to attempt it himself, but this was met with a storm of disapproval. During the night, the patient was being attended by young Crosby, and the following conversation is quoted. "Look here, young man, did you ever cut off a leg?" "No sir, but I should like to." "Will you cut off mine?" "Yes, if you will let me." "Well, young man, if I live till morning you shall cut off my leg, and I will take the chances." In the morning, all the elders joined in protest against the operation, and Dixi's father said, "Don't do it, Dixi, you can't succeed and if the man dies they will kill you." But the patient was firm, and the student was ready. The leg was removed, and the man recovered.

During the following year, father and son were called in while at a distant village to see a man who had just had a severe accident to his leg, demanding amputation. The father was for giving it up, since he did not have his instruments with him. The more resourceful young Crosby sharpened a carving knife, filed a saw and did the amputation, which was successful.

These early incidents are pointers to his later teachings to his pupils. He often said to them,

"Depend on yourselves, young gentlemen, take no man's diagnosis, but see with your own eyes, feel with your own fingers, judge with your own judgment and be the disciple of no man"

Dr Crosby, although a surgeon by nature and by preference, was in no modern sense, a specialist. His professional and professorial labors included obstetrics as well as surgery, and his practice was enormous. Probably no man ever did more surgery in the State than he, and his surgical diocese extended from Lake Champlain to Boston.

Dr Crosby was the first to devise the method of reduction of dislocations of the phalanges by flexion, some of which had previously been irreducible. He was the first to open abscess of the hip joint. Most of his operations were done before he had ever seen them done by anyone. He was not a rapid or spectacular operator. His motto was that an operation was soon enough done when it was well enough done.

His brother speaks of him as follows:

[He was] a handsome, brilliant, cheery, chatty man. He could sing, tell a good story, was kindly and civil, had agreeable manners, had cultivated the proprieties of social life, and had entered upon a religious life, a combination forming ballast to stand any amount of sail or storm, any success or discouragement.

Dr Crosby passed his declining years in Hanover and passed on his mantle to his distinguished son and inseparable companion, Dr Alpheus Benjamin Crosby, affectionately known as "Dr Ben."

Edmund Randolph Peaslee was born in Newton on January 22, 1814. He was educated at New Hampton and Atkinson academies and at Dartmouth College and Dartmouth Medical School from which institution he graduated in 1838. He also received his M.D. degree from Yale. Following this, he studied extensively in Europe. He was then recalled to Dartmouth and appointed lecturer in anatomy and physiology. He taught at Dartmouth for twenty-seven years. He also taught at Bowdoin, at New York University College of Medicine and at Bellevue. He received an LL.D. from Yale University, as well as Dartmouth. He was a great scholar and a great gentleman. His greatest work was done in the field of gynecology, and his writings on gynecologic subjects were profound and scholarly. He was the first to remove both ovaries through a single incision. He was also the first to use vaginal drainage after a laparotomy. He was the first to flush out the abdominal cavity after laparotomy.

One of his friends described him as a tall, spare man, with a long beard, which early became snow white. In appearance, he was said to be as fragile

and as cold as an icicle from his own native land Oliver Wendell Holmes, who was his contemporary on the faculty of Dartmouth Medical School, said, "He looked as if his circulating capital might consist of a hundred or two red globules, with twice as many white ones, in a half a pint of serum, yet he outlived scores of prize-fighters." His appearance must have been deceptive, for he did an enormous amount of work for many years and was ever ready for more.

He was a most sympathetic and helpful friend and adviser of his students, all of whom he regarded and spoke of as "my boys."

He, too, was a fine Christian gentleman, with whom duty was the ruling passion. His contemporaries expressed their esteem for his character and scholarly attainments by making him president of the New Hampshire Medical Society, of the New York Academy of Medicine, of the Medical Society of the County of New York, of the New York Obstetrical Society, of the New York Pathological Society and of the American Gynecological Society; at the time of his death, he was a trustee of Dartmouth College and of the New York Academy of Medicine, corresponding fellow of the Obstetrical Society of Berlin and honorary fellow of the obstetrical societies of London, Boston and Louisville.

\* \* \*

These, in brief, are the lives of four great seekers for the light. Their careers suggest to me that oft-quoted passage:

Happy is the man that findeth wisdom, and the man that getteth understanding. For the merchandise of it is better than the merchandise of silver, and the gain thereof than fine gold. She is more precious than rubies, and all the things thou canst desire are not to be compared unto her. Length of days is in her right hand, and in her left hand riches and honour. Her ways are ways of pleasantness, and all her paths are peace.

Proverbs 3 13-17

## CLINICAL ASPECTS OF PAROXYSMAL RAPID HEART ACTION\*

LOUIS WOLFF, M.D.†

BOSTON

**N**UMEROUS publications bearing on the occurrence, mechanism and treatment of the various paroxysmal tachycardias are available. Analysis of the clinical manifestations of paroxysmal rapid heart action has not, however, received the attention it deserves. These data are essential to a complete understanding of the clinical problems created by these arrhythmias under different circumstances, of their prognosis and, to some extent, of their treatment. This study was made in an attempt to provide such data.

## MATERIAL

Data were obtained in 125 cases. Electrocardiograms were made during the paroxysm in every case but 1, and during normal rhythm in most. Ventricular rates were obtained from the electrocardiograms. There were 81 cases (65 per cent) of paroxysmal auricular fibrillation, 24 (20 per cent) of paroxysmal auricular tachycardia, 11 (8 per cent) of paroxysmal auricular flutter and 9 (7 per cent) of paroxysmal ventricular tachycardia. The types of heart disease‡ represented were: valvular heart disease (including 2 cases of subacute bacterial endocarditis), 25 cases (18 per cent) — 16 of these patients had mitral stenosis, 5 had aortic valvular disease without other valvular involvement, and 4 had mitral stenosis and aortic valvular disease (in 1 case, combined with tricuspid stenosis); angina pectoris of effort, 20 cases (14 per cent); acute or recent cardiac infarction, 24 cases (17 per cent); chronic arterial hypertension, with or without definite evidence of heart involvement (cases with concomitant valvular or coronary-artery disease are not included in this group), 23 cases (17 per cent); coronary-artery disease without angina of effort or acute or recent cardiac infarction, 10 cases (7 per cent) — the term "asymptomatic coronary disease" was applied to this group; hyperthyroidism, 8 cases (6 per cent); normal hearts, including 4 cases of hyperthyroidism, 25 cases (18 per cent); miscellaneous types, comprising 1 case each of acute simple fibrinous pericarditis, chronic cor pulmonale and acute cor pulmonale, 3 cases (2 per cent). Among

these cases, there were 19 patients with congestive failure and 2 with cardiac asthma.

The type of patient, ventricular rate, cardiac lesion, functional status of the circulation and the occurrence of palpitation, pulmonary congestion, angina pectoris (or status anginosus), circulatory collapse, congestive failure, various cerebral phenomena and embolism were analyzed, to determine what correlations existed. The available data in some cases were inadequate for clinical analysis; these cases, in addition to the others, were utilized to determine the influence of digitalis on the ventricular rate in paroxysmal auricular fibrillation.

## ASYMPTOMATIC CASES

Symptoms were not provoked by paroxysms of rapid heart action in 41 cases, almost one third of the entire series. The ages of the patients ranged from two to eighty years. This group included 5 cases (12 per cent) of paroxysmal auricular tachycardia, 28 (68 per cent) of paroxysmal auricular fibrillation, 5 (12 per cent) of paroxysmal auricular flutter and 3 (7 per cent) of paroxysmal ventricular tachycardia. The incidence of the various arrhythmias in this group is no different from that of the entire series.

Thirteen patients (32 per cent) had normal hearts, including 3 with hyperthyroidism (7 per cent); 10 (24 per cent) had hypertension with or without definite evidence of heart involvement (1 of these had hyperthyroidism); 10 (24 per cent) had acute or recent cardiac infarction; 4 (10 per cent) had asymptomatic coronary-artery disease; 2 (5 per cent) had rheumatic heart disease, and 1 had acute fibrinous pericarditis, 1 chronic cor pulmonale, 1 acute cor pulmonale and 1 angina pectoris. There was 1 case of congestive failure. The incidence of thyrotoxicosis, hypertension, acute or recent myocardial infarction and asymptomatic coronary disease is the same in this group as in the entire series of 125 cases, whereas the incidence of normal hearts is higher, and that of valvular disease, angina pectoris and congestive failure much lower than in the series as a whole. Embolism occurred in 4 cases. Extracardiac factors, which may possibly have had some bearing on the occurrence of the arrhythmia, were present in each case with a normal heart§: namely, anesthesia and

\*From the Cardiac Clinic, Beth Israel Hospital.

†Instructor, Courses for Graduates, Harvard Medical School; associate visiting physician, Beth Israel Hospital.

‡Classified according to etiology, the 125 cases accounted for 138 listings, this discrepancy being occasioned by the inclusion of some cases of coronary-artery disease in three different groups — asymptomatic, angina of effort and acute cardiac infarction — when observations were available during paroxysms of rapid heart action in more than one of these clinical states.

§There are, of course, many examples of paroxysmal rapid heart action in patients with normal hearts in whom obvious or apparent exciting causes are not evident.

surgery, hyperthyroidism, acute mediastinitis, bronchopneumonia, gangrenous appendicitis and subacute yellow atrophy of the liver.

The ventricular rates ranged from 80 to 250, but were 150 or less in 18 (44 per cent) and more than 170 in 8 (19 per cent) of the cases. Of the 18 patients with rates of 150 or less, the paroxysm of rapid heart action occurred postoperatively in 3, following hemiplegia in 1, and during the course of bronchopneumonia in 2. On the other hand, of the remaining 23 cases with rates exceeding 150, 9 were postoperative; 1 patient had subacute bacterial endocarditis, 1 had gangrenous appendicitis, 1 had acute rheumatic fever, and 1 had bronchopneumonia. Seven of the 8 cases in which the rate exceeded 170 were postoperative. Only 11 cases were not postoperative or did not have extracardiac disease, and in 10 of these the ventricular rate was less than 170; none of these patients had normal hearts. In 3 of the cases with embolism, the ventricular rate was 140 or less.

#### CASES WITH PALPITATION

Palpitation was the sole symptom provoked by paroxysmal rapid heart action in 17 cases. The ages of the patients ranged from twenty-one to sixty-one years. Of these, there were 3 cases (18 per cent) of paroxysmal auricular tachycardia, 13 (76 per cent) of paroxysmal auricular fibrillation, and 1 (6 per cent) of paroxysmal auricular flutter. The incidence of the various arrhythmias in this group differs from that of the entire series of 125 cases only in the absence of ventricular tachycardia. Eight patients (47 per cent) had normal hearts, 4 (24 per cent) had hypertension, 4 (24 per cent) had rheumatic heart disease, and 2 (12 per cent) had angina pectoris—1 with rheumatic heart disease. The occurrence of hypertension, rheumatic heart disease and angina pectoris was the same in this group as in the entire series of 125 cases, whereas the incidence of acute or recent myocardial infarction was much less and, in normal hearts, much greater than in the entire series. There was no case of congestive failure or embolism.

The ventricular rate was 150 per minute, or less, in 11 (65 per cent) of the cases, and more than 170 in only 1 case. In contrast to the group without symptoms, there were no postoperative cases, and the only extracardiac conditions were a lung tumor and carbon monoxide poisoning. Moreover, 4 patients were described as "nervous," and 1 was having menopausal symptoms. Of the 8 patients with normal hearts, 3 were nervous, 1 had a lung tumor, and 1 had carbon monoxide poisoning. The ventricular rates in the 2 cases of angina pectoris were 124 and 140, respectively, and

in the 4 cases of rheumatic heart disease 124, 160 to 180; 140, and 110 to 130, respectively.

#### CASES WITH PULMONARY CONGESTION

Dyspnea, wheezing, pulmonary edema and hemoptysis may be provoked by paroxysmal rapid heart action. After exclusion of cases of congestive failure and angina pectoris, there remain 11 in which one or more of these symptoms were observed during paroxysms of rapid heart action.

Mitral stenosis was present in 10 cases, and hyperthyroidism in 1. The paroxysm of rapid heart action in the latter occurred during an acute illness characterized by fever, marked but temporary dilatation of the heart and pericardial and pleural friction rubs; following subsidence of the acute condition and control of the hyperthyroidism by thyroidectomy, numerous paroxysms of auricular fibrillation, during a period of eleven years, failed to provoke dyspnea. There were 9 cases of auricular fibrillation, and 2 of auricular flutter. The slowest ventricular rate, 140 per minute, was observed in 2 cases, whereas in the rest, the rate was 150 or more. Embolism complicated the arrhythmia in 4 cases. The ages ranged from nineteen to fifty-five years.

However, not all patients with mitral stenosis exhibit manifestations of pulmonary congestion during paroxysms of rapid heart action. It was not present in 4 cases. In 3, the ventricular rates were 124, 140, and 110 to 130, respectively, and in only 1 was the rate greater than 150 (160 to 180).

#### CASES OF ANGINA AND CORONARY-ARTERY DISEASE

Angina pectoris was induced by paroxysmal rapid heart action in 15 cases. The ages in this group ranged from forty-four to seventy-five years. There were 4 cases (27 per cent) of paroxysmal auricular tachycardia, 10 (67 per cent) of paroxysmal auricular fibrillation, and 1 (6 per cent) of paroxysmal ventricular tachycardia. It is clear that the incidence of the various arrhythmias in this group is not significantly different from that in the entire series of 125 cases. The ventricular rate was 150 per minute or more in 12 cases, 140 in 2, and 120 in 1. Embolism complicated the arrhythmia in 2 patients with paroxysmal auricular fibrillation. There were 2 cases of mitral stenosis, with evidence of coronary-artery disease in 1, and 1 case of hyperthyroidism in which a routine post-mortem examination showed normal coronary arteries. Hypertension was present in 5 cases. Twelve patients gave a clear history of angina on effort, but no such history was obtained in 3 cases. In one case, paroxysms of auricular tachycardia recurred for thirty-six years without induc-

ing anginal pain; finally, however, although angina of effort had never yet been experienced, a paroxysm provoked pain. A short time after this episode, cardiac infarction occurred, and following recovery from the acute condition, angina was induced both by effort and by paroxysmal rapid heart action. Another case was similar, in that angina was induced by paroxysms of rapid heart action, but not by effort; it differed in one important aspect, however: cardiac infarction did not supervene, despite the lapse of considerable time. This patient was elderly and crippled by arthritis. The first attack of paroxysmal auricular fibrillation in still another case provoked angina pectoris, which had never been produced by effort. However, shortly following this event, there was an attack of cardiac infarction, uncomplicated by any disturbance of the heart rhythm. During convalescence, a paroxysm of auricular fibrillation failed to produce any symptoms but palpitation. In none of these cases was the variation in response to paroxysmal rapid heart action ascribable to a change in the ventricular rate.

In contrast to these 15 cases are 3 in which paroxysmal rapid heart action failed to induce angina pectoris, although effort did provoke this syndrome. The ventricular rates were 124, 140 to 145, and 140 per minute, respectively.

In 8 cases with significant coronary-artery disease but without a history of angina on effort or acute or recent cardiac infarction, it is noteworthy that paroxysmal rapid heart action did not induce angina pectoris. In 6 cases, the ventricular rates were quite rapid, being 215, 175, 166, 190, 200 and 150 per minute, respectively. Significant coronary-artery disease was revealed by post-mortem examination in 4 cases, and by a history of old cardiac infarction antedating the occurrence of paroxysmal ventricular tachycardia in the other 2. The 2 remaining cases of asymptomatic coronary-artery disease had ventricular rates of 120, and 120 to 140, respectively.

Twenty-four cases of acute and recent cardiac infarction were complicated by paroxysmal rapid heart action—3 (13 per cent) by paroxysmal auricular tachycardia, 13 (54 per cent) by paroxysmal auricular fibrillation, 4 (17 per cent) by paroxysmal auricular flutter, and 4 (17 per cent) by paroxysmal ventricular tachycardia. The incidence of auricular flutter and ventricular tachycardia was higher than in the entire series of 125 cases, but otherwise there was no difference between this group and the entire series. The occurrence of paroxysmal tachycardia is unusual before the third day following the onset of cardiac infarction, the greatest incidence coming on or after the fifth day. Thus, of 18 cases studied ade-

quately, 14 exhibited paroxysmal rapid heart action three days to two months following acute cardiac infarction; in no case was anginal pain induced, even though the ventricular rate was 150 per minute, or more, in all but 3. None of these patients experienced anginal pain spontaneously or as the result of effort. In 1 case, angina of effort continued after an episode of myocardial infarction and was also induced by paroxysmal ventricular tachycardia at a rate of 187. In 3 cases, paroxysmal rapid heart action and cardiac infarction appeared to have a simultaneous onset. In 1 case, paroxysmal auricular tachycardia and cardiac infarction occurred simultaneously, and, as so often happens under these circumstances, the precise sequence of events remains uncertain; the significant fact is the continuance of the paroxysmal tachycardia for twenty-four hours following the cessation of pain. Four and a half hours after a similar onset in another case, the paroxysmal tachycardia ended, but pain and shock continued for three or four days. Prior to the onset of the attack in these 2 cases, angina on effort had never been experienced, and four years prior to the attack in the latter case, paroxysmal auricular tachycardia with a rate of 200 failed to induce angina pectoris. The third case was similar to these in that paroxysmal auricular fibrillation apparently induced angina pectoris in a patient who had never experienced such pain on effort, and the obvious fact soon emerged that cardiac infarction was in progress. The possibility that paroxysmal rapid heart action precipitated acute coronary thrombosis or cardiac infarction in these 3 cases must be considered. It has been suggested<sup>1</sup> that paroxysmal rapid heart action, by further impairing an already abnormal coronary circulation, may predispose to or precipitate acute coronary thrombosis or cardiac infarction; convincing evidence is difficult to obtain, but 2 cases in addition to those just described are suggestive. In these, pain occurred some hours after cessation of a paroxysmal arrhythmia; myocardial infarction was found at autopsy in both.

#### CASES OF CONGESTIVE FAILURE

Congestive failure was present in 19 cases, in 15 of which it was possible to estimate the effect of paroxysmal rapid heart action on the degree of failure. There were 6 cases (40 per cent) of paroxysmal auricular tachycardia, 5 (33 per cent) of paroxysmal auricular fibrillation, 2 (13 per cent) of paroxysmal auricular flutter, and 2 (13 per cent) of paroxysmal ventricular tachycardia. The ages ranged from thirty-four to sixty-eight years. Rheumatic valvular disease (including 1 case of sub-acute bacterial endocarditis) was present in 7 cases

(47 per cent), hypertension without additional etiologic factors in 4 (27 per cent), and coronary-artery disease in four (27 per cent). The ventricular rate was 150 per minute or more in 10 cases, 140 in 3, and 130 and 120, respectively, in 2. Embolism occurred in 1 case of paroxysmal auricular tachycardia and in 2 cases of paroxysmal auricular fibrillation, and in 1 case of mitral stenosis complicated by paroxysmal auricular flutter, autopsy revealed old splenic infarcts and terminal coronary thrombosis.

In 14 cases, there was noted, as a result of the paroxysms of rapid heart action, an increased severity of such manifestations as dyspnea, orthopnea, congested liver and edema, and a drop in the urinary output, or renal failure, coma and death, in some of these cases, there was a prompt and striking clinical improvement following the resumption of normal rhythm. Gross congestive failure was evident prior to the onset of tachycardia in all but 1 case, in which, however, chronic hypertension, cardiac enlargement and exertional dyspnea indicated the probability of incipient failure or poor cardiac reserve. Evidence of gross failure first appeared, and then rapidly progressed, at the end of ten days of paroxysmal auricular tachycardia with a ventricular rate of 210 per minute; rapid improvement followed resumption of normal rhythm. In an additional case, in which the ventricular rate was 120 per minute, the arrhythmia appeared to have no obvious influence on the functional status of the cardiovascular system.

#### CASES WITH CENTRAL-NERVOUS SYSTEM MANIFESTATIONS

Irrationality, confusion, psychosis, coma and convulsions may be observed during attacks of paroxysmal tachycardia. Six patients exhibited one or more of these manifestations. The ages ranged from sixty-one to seventy-one years. There were 2 cases of paroxysmal auricular tachycardia, 2 of paroxysmal auricular fibrillation, and 2 of paroxysmal ventricular tachycardia. Four patients had hypertension, and 2 had coronary-artery disease. There were 3 cases of congestive failure, 1 of cerebral embolism, 1 of pulmonary embolism, and 1 of pulmonary thrombosis. The ventricular rates were 150 to 200 per minute.

One patient was "euphoric and queer" before the onset of paroxysmal ventricular tachycardia, which precipitated an acute psychosis. In another, irrationality, which had been previously noted, was increased during a paroxysm of auricular tachycardia. Another patient showed signs of mental confusion accompanying an attack of auricular fibrillation, which was complicated by cerebral embolism. Paroxysmal auricular tachycardia in a

case of congestive failure brought about renal failure, which was followed by coma. Unconsciousness occurred as a transitory phenomenon at the onset of paroxysmal ventricular tachycardia in a patient with a ventricular rate of 190, whereas in another, unconsciousness and convulsions occurred at the end of a paroxysm of auricular fibrillation, presumably from cardiac standstill before the re-establishment of a normal sinus mechanism. In the last case, there were no heart sounds during the seizure, but unfortunately it was not possible to obtain an electrocardiogram during the period of apparent cardiac standstill.

#### CASES WITH VASCULAR COLLAPSE

Although a fall in blood pressure was commonly observed during paroxysmal rapid heart action, in only 15 cases did collapse occur. The ages ranged from thirteen to sixty-eight years. There were 5 cases (33 per cent) each of paroxysmal auricular tachycardia and paroxysmal auricular fibrillation, 3 (20 per cent) of paroxysmal auricular flutter, and 2 (14 per cent) of paroxysmal ventricular tachycardia. Four patients had normal hearts (1 with hyperthyroidism), 5 had mitral stenosis, 1 had free aortic insufficiency, 2 had angina pectoris, 2 had asymptomatic coronary artery disease, and 1 had recent cardiac infarction. Only 1 case of hypertension (in a patient with mitral stenosis) occurred in this group. Four patients had congestive failure. Embolism complicated the arrhythmia in 5 cases. The ventricular rate was 200 per minute or more in 7, or almost half the cases, and was less than 150 in only 2.

#### CASES OF EMBOLISM

Embolism complicated the paroxysmal arrhythmia in 18 cases; pulmonary-artery thrombosis occurred in 1 case. The ages ranged from nineteen to sixty-eight years. All types of arrhythmia were represented. 2 cases (11 per cent) of paroxysmal auricular tachycardia, 11 (58 per cent) of paroxysmal auricular fibrillation, 3 (16 per cent) of paroxysmal auricular flutter, and 3 (16 per cent) of paroxysmal ventricular tachycardia. Mitral stenosis was present in 7 cases, coronary artery disease in 7, hypertension in 4 (with mitral stenosis in 1), and a normal heart in 1. Four patients were in congestive failure. Pulmonary embolism occurred in 16 cases, but the diagnosis was doubtful in 2, cerebral, renal, splenic and axillary embolisms were also observed. The ventricular rates ranged from 120 to 220 per minute. Embolism preceded, and probably provoked, the arrhythmia in 3 cases, and was followed by vascular collapse in 7. Dyspnea occurred in only 5 cases, and hemoptysis in 2, all being cases of mitral stenosis;

pulmonary edema occurred in 1 case of mitral stenosis. In 2 cases, the advent of embolism appeared to provoke no symptoms; the ventricular rate was 120 and 140 respectively, in these.

#### EFFECT OF DIGITALIS

Digitalis was being taken by 29 patients prior to the onset of a paroxysm of auricular fibrillation in which observations could be made. The ventricular rates in these cases were compared with those in 52 patients who did not receive digitalis. The paroxysms observed numbered 30 and 55, respectively; the ventricular rate was less than 140 in 14 (47 per cent) and more than 140 in 16 (53 per cent) of the paroxysms in the former group, and less than 140 in 11 (20 per cent) and more than 140 in 44 (80 per cent) in the latter group. In 6 cases, observations of the ventricular rate were made in paroxysms of auricular fibrillation both before and after the administration of digitalis. The ventricular rate was significantly lower after digitalization in 4 of these and was unchanged in 2. The ventricular rate in 16 fully digitalized cases was less than 140 in 7, and 140 or more in 9; in 7 cases that were overdigitalized (excessive amounts of the drug, or digitalis intoxication), the ventricular rate was less than 140 in 4, and 140 or more in 3; in 2 partially digitalized cases, the rates were 140 and 130, respectively; in 4 cases, the amount of digitalis taken was unknown.

Among the 15 digitalized cases in which the ventricular rate was 140 or more, normal hearts were present in 4, acute cardiac infarction in 1, hyperthyroidism in 1, and congestive failure in 3; in the last 3 cases, the ventricular rates were the slowest of this group—140, 140 and 150, respectively. The group of 14 with ventricular rates under 140 contained no patients with normal hearts, 2 with hyperthyroidism (1 of whom received iodine in addition to digitalis), 2 with acute cardiac infarction, and 5 with congestive failure.

Digitalis administered between paroxysms of auricular fibrillation is effective in controlling the ventricular rate during the paroxysm in some, but not in all, cases. The ventricular rate was significantly slow in 20 per cent of patients who had not had any digitalis, a fact that should be considered in appraising the above data; moreover, in 2 cases in which digitalis appeared to be effective, other factors were operative—one patient, with hyperthyroidism, received iodine in addition to digitalis, and the other had a 2:1 auriculoventricular block. It is obvious that in more than half the patients digitalis did not prevent ventricular rates that were rapid enough to induce symptoms, even when excessive amounts of the drug were used. Digitalis is least effective in those with normal hearts, and displays its greatest influence on the

ventricular rate in patients with congestive heart failure.

Since it is not my purpose to provide an elaborate presentation of treatment, the consideration of the effect of digitalis and other therapeutic agents on the other arrhythmias is omitted.

#### DISCUSSION

Correlation of certain symptom groups with the ventricular rate, type of patient, cardiac lesion and presence or absence of embolism and congestive failure (Table 1) reveals that most of the symptoms are provoked under definite conditions and relations; and there is thus created, within broad limits, a fixed and uniform clinical pattern. The remaining symptoms, which are not susceptible to such correlation, must be differentiated from the cardinal manifestations of paroxysmal tachycardia and regarded as minor or noncharacteristic; some of these are nausea, vomiting, weakness, dizziness, precordial pain or aching, sweating, feeling of warmth, faintness, apprehension, nervousness, polyuria, fever and leukocytosis; a slight to moderate drop in blood pressure is very common, and rarely, in cases of congestive failure, the blood pressure may rise. Following a paroxysm of auricular tachycardia pain, tenderness and swelling of the left shoulder, accompanied by fever, leukocytosis and rapid sedimentation rate, were observed in 1 patient; these manifestations rapidly subsided.

The ventricular rate and, to a lesser extent, the type of arrhythmia are significant in determining symptoms. Symptoms are not often provoked by rates under 150 per minute, which may be regarded as the critical level, unless embolism complicates the paroxysm. With extremely rapid ventricular rates, on the other hand, symptoms are almost always induced, regardless of the type of heart lesion and even if the heart is normal. When symptoms fail to appear during paroxysms with rates somewhat above the critical level, the explanation is usually to be found in the type of patient, who is "insensitive" naturally or as the result of grave illness, or has been rendered so by heavy sedation. The group in which palpitation occurs as the only symptom differs most strikingly from the asymptomatic one in relation to the type of patient; "sensitiveness" is common, and conditions requiring heavy sedation are absent. The lack of symptoms other than palpitation is to be explained on the basis of the ventricular rate.

A comparison of the ventricular rates in the different types of rapid heart action is of some interest. The slowest rate (excluding cases of auricular fibrillation), 124, occurred in paroxysmal auricular tachycardia; the fastest rate, 260, in a case of auricular flutter with 1:1 ventricular response. The ventricular rate in auricular fibrillation is usually under 170, and only rarely 200 or more. The

fastest rates occur in auricular flutter during periods of 1:1 response. In paroxysmal auricular tachycardia, the ventricular rate, as a rule, does not exceed 220. Excessively rapid ventricular rates, in the vicinity of 300, were not observed in the present series, but many cases are on record. These are usually, probably always, examples of auricular flutter with 1:1 ventricular response.<sup>2-21</sup> Two cases of auricular flutter with 1:1 ventricular re-

gessive heart failure. The characteristic response in cases of compensated mitral stenosis consists of dyspnea, orthopnea, asthma, pulmonary edema and hemoptysis. These manifestations usually occur when the ventricular rate is 150 per minute or more; pulmonary congestion is not induced when the ventricular rate is well under this level, but is rarely absent when it is exceeded. These clinical phenomena, in some cases, may be less

TABLE 1. *Correlation of Clinical Data.*

SYMPTOM OR COMPLICATION	HEART LESION	VENTRICULAR RATE	TYPE OF PATIENT	EMBOLISM
Asymptomatic	None, or any type	Usually 150 per minute or less	'Insensitive'	Uncommon
Palpitation	None, or any type	Usually 150 per minute or less	'Sensitive'	Never
Pulmonary congestion	Mitral stenosis	Usually more 150 per minute or		Common
Angina pectoris	Angina pectoris of effort, occasionally, aortic valvular disease	Usually more 150 per minute or		Uncommon
Central nervous system manifestations				
Loss of consciousness, with or without convulsions	None, or any type	Usually 200 per minute or more (cardiac standstill) Rate unimportant		May occur (not essential) Always (cerebral)
Mental confusion or acute psychosis	None, or any type, hypertensive and coronary disease and congestive failure common	Rate unimportant if cerebral embolism occurs, otherwise usually 150 per minute or more	Functional nervous disorders or organic cerebral disease	May be causative (not essential)
Coma	Congestive failure, renal failure	Usually 150 per minute or more		May be causative (not essential)
Congestive failure	Any type (pre existing congestive failure or very poor reserve)	Usually more 150 per minute or		Common
Vascular collapse	None, or any type Aortic valvular disease None, or any type	Usually 200 per minute (less in elderly patients) Rate unimportant Rate unimportant		May occur (not essential) May occur (not essential) Always
Embolism	None, or any type (mitral stenosis commonest)		Commonest with auricular fibrillation, may occur with auricular flutter or paroxysmal tachycardia	

sponse occurred in this series, and may be added to those already reported.<sup>22, 23</sup>

The significance of the type of rhythm is seen in auricular fibrillation and paroxysmal ventricular tachycardia. Embolism is much more frequent in the former than in all the other types of arrhythmia, and whereas the immediate consequences of paroxysmal ventricular tachycardia are no different from those in the other arrhythmias under identical conditions, the mortality is highest in this group, probably on account of the seriousness of the underlying heart condition, or the conversion of the paroxysmal ventricular tachycardia into ventricular fibrillation.

The influence of the heart lesion and of the functional status of the circulation on the type of clinical response to paroxysmal rapid heart action is decisive, and may be best observed in cases of mitral stenosis, angina pectoris of effort and con-

gestive heart failure. The characteristic response in cases of compensated mitral stenosis consists of dyspnea, orthopnea, asthma, pulmonary edema and hemoptysis. These manifestations usually occur when the ventricular rate is 150 per minute or more; pulmonary congestion is not induced when the ventricular rate is well under this level, but is rarely absent when it is exceeded. These clinical phenomena, in some cases, may be less pronounced when, in addition to mitral stenosis, there is aortic valvular disease, congestive failure or vascular collapse. The clinical and x-ray manifestations of the pulmonary congestion disappear with remarkable rapidity when normal rhythm is resumed. A spontaneous diuresis may then be observed, even though there is a complete absence of manifest edema or other fluid accumulations (except in the lungs). The extent of the response, or the lack of it, depends not only on the ventricular rate but also on the degree of mitral stenosis.

In compensated valvular heart disease other than mitral stenosis, regardless of the ventricular rate, pulmonary congestion is not induced.

In cases of congestive failure and angina pectoris, as well as in cases of mitral stenosis, dyspnea may be one of the consequences of paroxysmal rapid heart action. When it occurs in angina pectoris, it accompanies anginal pain, which is the

leading symptom induced by the tachycardia, and is no different from the dyspnea experienced in attacks of angina that occur spontaneously or are provoked by effort. Similarly, in congestive failure, dyspnea, like the other manifestations of myocardial insufficiency, — congested liver, edema and so forth, — is increased in severity but is evident before the onset of the tachycardia.

Paroxysmal rapid heart action increases the severity of pre-existing congestive failure and may precipitate gross congestive failure in cases with limited cardiac reserve if the paroxysm is unduly prolonged or the ventricular rate is extremely rapid. When the paroxysms are transitory or the ventricular rates are considerably below 150 per minute, no effect on congestive failure is observed. The essential factor in this group of cases is not the type of heart lesion, but the functional status of the cardiovascular system. Embolism does not occur so preponderantly in cases of paroxysmal auricular fibrillation and of mitral stenosis when congestive failure is present as when it is absent. When symptoms are stated in publications concerning paroxysmal tachycardia, dyspnea or other manifestations of congestive failure are usually given a prominent place. Perusal of individual case reports often reveals the existence of mitral stenosis, congestive failure and angina pectoris. This coincides with my own findings, and these cases will not be reviewed here. There are, however, many case reports in which these conditions are not reported to be present, even though the clinical data are fully recorded, but in which dyspnea or other manifestations of congestive failure first appear after the onset of paroxysmal rapid heart action.<sup>2, 4, 7-9, 12, 14, 16, 18, 19, 21, 24-26</sup>

The cases referred to are selected as examples of dyspnea or congestive failure brought on by paroxysmal rapid heart action in patients who, prior to the onset of tachycardia, presumably had normal hearts; these furnish a striking contrast to the cases reported in this paper and indicate the need for careful observation of additional clinical material before the relation of dyspnea and failure to various factors can be fully expressed. From the recorded case histories, however, certain conclusions appear to be justified. There is a preponderance, in this group, of infants and young children. In most cases, the ventricular rates were extremely rapid, attaining or approaching the highest rates known to occur; in many, the paroxysms were unusually long. Infection preceding the onset of tachycardia was commonly observed, and was followed by clinical evidence of acute myocardial disease in some and by post-mortem demonstration of diffuse myocarditis in others. In some of the recorded cases, conditions besides car-

diac disease have been responsible for the occurrence of dyspnea. Finally, in most patients with extremely rapid heart rates, auricular flutter is responsible for the tachycardia; the extreme rate is due to a paroxysm of 1:1 ventricular response in the course of an established flutter.<sup>22</sup>

Patients who experience angina pectoris on effort invariably suffer similar attacks during paroxysms of rapid heart action, provided that the ventricular rate is 150 or more per minute; pain is never provoked if the rate is well under 150, unless digitalis has been taken. It is noteworthy that in cases of extensive coronary disease without angina pectoris, paroxysmal tachycardia, even with extremely rapid rates, does not induce anginal pain. Only occasionally does paroxysmal rapid heart action induce anginal pain in those who have never experienced angina on effort. This is true in elderly crippled patients whose activity is seriously hampered and, rarely, in those with aortic insufficiency; it may constitute a premonitory warning that acute cardiac infarction is soon to occur or is already in progress. Under the latter two conditions, the possibility that the paroxysm of rapid heart action has precipitated acute coronary thrombosis or cardiac infarction must be considered. Paroxysmal rapid heart action complicating acute cardiac infarction does not materially influence the pain, which may cease even though the tachycardia continues unabated.

When one appraises an attack of paroxysmal rapid heart action accompanied by angina pectoris (or status anginosus), two possibilities must be considered: the attack may represent the induction of angina by paroxysmal rapid heart action or acute coronary thrombosis or cardiac infarction may have taken place. If the history reveals the past occurrence of angina on effort, it is probable that the former situation prevails, notwithstanding the presence of fever, leukocytosis and even embolism; the pain, fever and leukocytosis (if there is no embolism) promptly disappear on cessation of the tachycardia. On the other hand, if angina on effort has never occurred, serious consideration must be given to the diagnosis of acute cardiac infarction. If the pain continues after normal rhythm has been resumed, if the pain disappears while the tachycardia remains in progress without a significant lowering of the ventricular rate, if there is vascular collapse despite a moderate ventricular rate, and if the temperature and white cell count do not rapidly revert to normal level on cessation of the tachycardia, it is highly probable that acute cardiac infarction has occurred. Rarely, paroxysmal rapid heart action may begin after the onset of angina pectoris, of which it is then a complication.<sup>27</sup>

The significance of the cardiac lesion is illustrated in those patients who have had paroxysmal tachycardia for a long time—in some cases twenty-five to fifty years. Repeated attacks may fail to induce symptoms until, years after the onset of paroxysmal rapid heart action, significant coronary-artery disease and angina of effort develop, with consequent induction of angina during paroxysms of tachycardia.

Three factors appear to be significant in the genesis of vascular collapse: extremely rapid ventricular rates, embolism and aortic valvular disease. Extremely rapid ventricular rates and embolism occur in half and one third of the cases, respectively. When extremely rapid ventricular rates are attained, all other factors may be absent, and the heart may be normal. If embolism complicates the tachycardia, the ventricular rate and the type of cardiac lesion are not significant. In the presence of aortic valvular disease, vascular collapse may occur, even though the ventricular rate is significantly under 150 per minute and embolism is absent. Although the 2 patients with slow ventricular rates were in congestive failure, it is unlikely that the latter is essential in the production of vascular collapse when the ventricular rate is slow; one patient had aortic valvular disease, and the other case was complicated by embolism. The age factor appears to be largely unimportant. Occasionally, in elderly patients, vascular collapse may occur with only moderately rapid ventricular rates, even though other contributing factors are not evident.

Cerebral manifestations are not uncommon. The age range in this group is higher than in the other groups, and the incidence of hypertension, congestive failure, embolism (or arterial thrombosis) and functional or organic cerebral disease is high. The events witnessed in this group are associated with various circumstances, which may be summarized as follows: Unconsciousness, with or without convulsions, may be provoked by a single factor,—extremely rapid ventricular rates or transitory cardiac standstill,—and may be seen in healthy young adults with normal hearts. When cerebral embolism complicates paroxysmal rapid heart action, loss of consciousness and convulsions or other cerebral manifestations may occur, regardless of the ventricular rate. In patients with functional nervous disorders or organic cerebral disease, paroxysmal arrhythmias with ventricular rates usually greater than 150 per minute may provoke confusion, irrationality or acute psychosis. It may therefore be stated that the induction of central nervous system manifestations depends on three factors: the ventricular rate, the "type" of patient and the organic cerebral disease. The type of heart lesion is not important, since patients

with normal hearts, as well as those with various types of heart disease, are seen in this group; the high incidence of hypertension and coronary-artery disease is probably explained by the frequency with which functional and organic cerebral disorders accompany these conditions. The best examples of cerebral manifestations are probably seen in cases with unusually rapid ventricular rates, as in auricular flutter with 1:1 ventricular response, when the rates approach  $300^{4, 6, 10, 11, 17, 22, 26-32}$ . On the other hand, even with extremely rapid ventricular rates, cerebral or other manifestations may be singularly absent.<sup>2, 6, 13</sup> Under cerebral manifestations, Barnes<sup>30</sup> includes vertigo, hemianopsia, temporary blindness, fainting, falling, with or without loss of consciousness, and epileptiform seizures.

Embolism may complicate any type of paroxysmal rapid heart action, occurring in patients of any age and with any type of heart disease. It is commonest in the presence of mitral stenosis and with auricular fibrillation. The most frequent consequences are circulatory collapse and dyspnea, the latter, in this series, occurring only in cases of mitral stenosis. The most frequent site of embolism is the lungs. Although embolism complicates the arrhythmia in most cases, the former may precede and provoke the latter, this sequence occurred in 1 case of auricular fibrillation and in 2 of auricular flutter.

Paroxysmal rapid heart action may cause death as the result of heart failure, vascular collapse, embolism, renal failure, the conversion of the paroxysmal arrhythmia into ventricular fibrillation, or cardiac standstill.

Paroxysmal auricular tachycardia may occur in patients who at other times exhibit carotid sinus sensitivity. Nevertheless, pressure exerted over the carotid sinus may not influence the paroxysm. In some cases, this failure of response may be associated with a marked fall in blood pressure, which accompanies the tachycardia, whereas in others the same phenomenon is observed even though a drop in blood pressure has not occurred.

The four types of paroxysmal rapid heart action with which this report is concerned were associated with many different extracardiac conditions, especially in the patients with normal hearts: gastrointestinal disturbances (including peptic ulcer, gall bladder disease, carcinoma, acute gangrenous appendicitis and incarcerated hernia), anesthesia, surgery, infections (pneumonia, peritonitis, pericarditis, acute mediastinitis, pulmonary tuberculosis, chronic pulmonary infections, pleuritis, wound sepsis, furunculosis and acute tonsillitis), lung tumor, embolism, trauma, carbon monoxide poisoning, exertion (including such activities as turning or twisting of the body, laughing and sneezing), emotional

upsets, hyperthyroidism, menopausal disturbances, acute yellow atrophy of the liver and the use of digitalis. The relation of many of these conditions to the inception of auricular fibrillation is discussed, and the literature reviewed, by Parkinson and Campbell.<sup>27</sup>

There is considerable experimental and clinical evidence that digitalis may provoke or prolong paroxysms of auricular fibrillation.<sup>17, 27, 33-39</sup> For this reason alone, one may doubt the advisability of routine digitalis therapy in such cases. Furthermore, the ventricular rate is not always rapidly controlled, and it is of greater fundamental value to abolish the abnormal rhythm. Digitalis is not indicated in paroxysms of auricular fibrillation when the ventricular rate is less than 150 per minute, and in any event, regardless of the rate, if symptoms are not provoked by the paroxysm. The wisdom of continually using digitalis for the avowed purpose of assuring a slow ventricular rate whenever a paroxysm of auricular fibrillation occurs may be seriously questioned on the basis of the evidence. In a considerable number of cases, under these circumstances, a ventricular rate sufficiently slow to prevent the development of symptoms is not achieved.

#### SUMMARY

The clinical data of 125 cases of paroxysmal rapid heart action are analyzed.

The cardinal symptoms and signs are correlated with certain significant variables in the individual patient. It has been shown that the various phenomena occurring in paroxysmal rapid heart action arise under definite conditions and relations and thus create, within broad limits, a uniform clinical pattern.

The cardinal manifestations of paroxysmal rapid heart action are palpitation, pulmonary congestion (dyspnea, wheezing, pulmonary edema and hemoptysis), angina pectoris or status anginosus, congestive failure, vascular collapse, cerebral manifestations and embolism. In many cases, no symptoms are provoked.

The significant variables are the type of patient, the heart lesion, the functional status of the circulation, the ventricular rate (and in a lesser degree the type of rhythm) and the presence or absence of embolism.

The most characteristic responses occur in cases of mitral stenosis, angina pectoris and congestive failure.

The critical level of the ventricular rate is approximately 150 per minute. As a rule, manifestations are not provoked below this level. The characteristic consequences of extreme rates are discussed.

The effect of digitalis on the ventricular rate in cases of paroxysmal auricular fibrillation is discussed.

## MEDICAL PROGRESS

### THE CHEMICAL MEASUREMENT AND CONTROL OF CLINICAL VITAMIN DEFICIENCY\*

WILLIAM T. SALTER, M.D.†

NEW HAVEN, CONNECTICUT

THE past decade has contributed not only a more detailed description of clinical deficiency disease, including several syndromes and symptoms hitherto unrecognized in man,<sup>1</sup> but also significant advances in the knowledge of the chemical nature of these interesting accessory food substances. In general, gross vitamin deficiencies continue to be diagnosed through the aid of the five senses, in addition to common sense. Nevertheless, the use of objective tests is desirable for three purposes: to confirm clinical diagnosis and so maintain a high standard of accuracy therein; to serve as a court of appeal in doubtful cases, particularly in the region of partial vitamin collapse that Minot<sup>2</sup> has termed the "twilight zone of vitamin deficiency"; and to check the effectiveness of therapy. The need for the first of these objectives is obvious. The need for the last two is becoming clearer as physiologic studies are demonstrating that vague apathies and lack of efficiency are produced by incipient vitamin lack, which causes symptoms commonly known as "subclinical." For example, for many years it has been known that a patient with pellagra may show no *pelle agra* until exposure to actinic rays is used to bring out the peculiarity of the condition.

In the field of neuropsychiatry, in particular, the lack of vitamin B complex is becoming more and more important. Thus, Jolliffe and his associates<sup>3</sup> have demonstrated that on a thiamin-deficient diet healthy interns in a hospital underwent a considerable loss of "energy" and even showed changes in personality within a relatively few days. Indeed, many patients in severe illness are subject to a lack of vitamin intake not unlike that which these experimental observations produced, and it remains to be seen to what extent severe or debilitating disease produces a similar change in personality through lack of these essential substances. In the intricate fields of neurasthenia and psychoneurosis, this problem may also complicate the picture. For this reason, there is a wide opportunity for the use of chemical methods

in the investigation of routine patients, even those whose symptomatology is not very dramatic. Such determinations, of course, should not replace careful dietary histories or painstaking physical diagnosis. They should be used in a confirmatory sense.

With the development of knowledge concerning the nature of the vitamins have come appropriate chemical methods for their determination. These chemical procedures are far more practical and convenient than the older mammalian assays, which are so costly and time-consuming that for clinical purposes they are not practical. To be sure, they may still be used occasionally to check the chemical methods employed for clinical purposes. Likewise, in recent years, the use of micro-organisms for biologic assay has extended the practicability of the biologic method for testing vitamin concentration. For example, in the assay of biotin, the vitamin universally needed for growth, it is possible to measure extraordinarily small amounts of material. One makes the measurement by studying the effects on the growth of micro-organisms of amounts of this substance that are of the order of a small fraction of a millionth of a gram. If, however, practical application in clinical cases is to be hoped for, it will probably come chiefly through the use of chemical tests.

Two main difficulties have stood in the way of the development of such reactions. The first is that such extraordinarily minute amounts of the material are needed in nature; this follows from the fact that the vitamins in general are to be thought of as natural catalysts. Indeed, some of them are known to contribute the precise prosthetic groups that determine the specificity of enzymes. In this respect, they are analogous to the haptophore groups that Ehrlich postulated for antibodies. The second difficulty is that, obviously, to detect such small amounts of material by a practical chemical procedure, one often has to sacrifice a certain degree of specificity. Therefore, so far as chemical specificity has been sacrificed, the method is subject to error. In spite of these difficulties, tests are already available that can be used in clinical cases; they are simple enough to be performed in any large clinic that has in operation research laboratories for routine clinical studies.

Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C. Thomas Company, 1941, \$4.00).

\*This Yale University School of Medicine Professor

†Professor of pharmacology, Yale University School of Medicine.

Several of the vitamins have been discovered so recently that as yet their detection is largely a biologic affair. Accordingly, it is not practical to expect their analysis in clinical cases for some time. Of the better known vitamins, however, simple chemical methods have now been developed for carotene and vitamin A, for thiamin, for riboflavin, for ascorbic acid and for nicotinic acid. Fortunately, it is becoming progressively clearer that vitamin deficiency, as it is encountered clinically, is usually multiple. Accordingly, in many cases, if one detects the lack of one of these well-known vitamins and thus confirms the noncommittal diagnosis of "vitamin deficiency," there are likely to be deficiencies of other vitamins not specifically tested. For this reason, the administration of the one pure vitamin recognized as lacking in a given case may remedy only part of the patient's difficulty. If, however, a well-balanced diet is included in the therapeutic regimen, natural food-stuffs will probably correct any serious deficiency of some of the less well-known vitamins. More experience is needed in this field, but it is already clear, for example, that in clinical pellagra there is a deficiency, usually of nicotinic acid, but frequently also of thiamin or riboflavin. Indeed, these secondary deficiencies account for the wide differences in symptomatology and in response to therapy of individual cases.

#### TECHNICAL POSSIBILITIES

In general, two main procedures are available for detecting vitamin deficiency chemically—the first, through the determination of the concentration of vitamin in the blood, and the second, through the study of urinary excretion. At one time, it was thought that a low vitamin concentration in the blood strongly indicated a vitamin deficiency. This is now known not necessarily to be so. For example, the investigations of Mindlin and Butler<sup>4</sup> have shown that the vitamin C content of the plasma may undergo considerable fluctuations for a short time in fairly normal subjects, and that the plasma level may drop to very low concentrations while the tissue reservoirs of vitamin are still entirely adequate. It may be said, therefore, that whereas a high vitamin level in the blood ordinarily rules out deficiency of the antiscorbutic vitamin, a low level does not necessarily mean that the patient's tissues are really suffering from its lack. Furthermore, with the other vitamins, a normal blood concentration may exist in the presence of undoubted deficiency, as will be explained presently.

In such cases, the study of urinary secretion is of more value. To be sure, collection of urine involves extra work, and is subject to the errors of decomposition and loss. Nevertheless, if one finds

that a patient is still excreting considerable amounts of vitamin in the urine, one is assured that there is an excess of that vitamin in the organism. On the contrary, if the vitamin excretion is low, one may assume that no such excess of the essential factor exists. Furthermore, urinary studies may be extended by the use of the so-called "vitamin-tolerance test." In this technic, a known amount of vitamin is administered, and its fate by urinary excretion is subsequently determined. If the tissues have been hungry for vitamins, they will retain a large portion of the vitamin administered. If, on the other hand, the tissues have already been replete with vitamin stores, they will fail to retain so considerable a portion of the vitamin administered.

In such a test, if the vitamin is administered orally, one must take special precautions to exclude conditions that would interfere with the absorption of the vitamin by the alimentary tract. The same precautions hold for subcutaneous administration in edematous patients. On the other hand, it is not always desirable to administer vitamins by vein. For example, even in vitamin-deficient persons, if thiamin is administered intravenously, a large amount may run out through the kidneys before the tissues have a sufficient opportunity to affix the thiamin. It will be apparent that it is easier technically to rule out vitamin deficiency than to verify it, and that whenever such a test reveals vitamin deficiency, the technic must be scrutinized carefully and the test repeated, to exclude, so far as possible, technical errors such as those discussed.

#### ANALYTICAL METHODS

So far as the chemical procedures now available are concerned, it must be remarked at the outset that there are frequently two or more competing methods for the determination of a given vitamin. In certain cases, one must weigh the expense of a complicated apparatus like a spectrophotometer against excessive labor costs or fatigue when a more tedious procedure is used. In other cases, a test requiring a considerable degree of skillful technical manipulation may have to be abandoned in favor of a simpler but more costly one. For this reason, the choice of the methods mentioned below is at best arbitrary, but in my opinion and that of my associates, they offer the best compromise between the various factors described.

Whatever method is chosen, it is always well to repeat the determination in cases suggesting vitamin deficiency before administering therapy, and to repeat the test at various intervals after the therapy is begun. This is especially desirable in cases in which the so-called "conditioned vitamin deficiency" is suspected. This sort of de-

ciency, which occurs when the dietary history is apparently adequate, has been described by Strauss,<sup>5</sup> Richardson<sup>6</sup> and Salter.<sup>7</sup> It is particularly common, as Castle et al.<sup>8</sup> have pointed out, in conditions involving the gastrointestinal tract. In these cases, owing to failure of absorption, the tissues suffer from vitamin lack although the diet contains an adequate amount of vitamin. If, in such circumstances, chemical responses in blood or urine can be recognized when the vitamin is administered, and especially if clinical improvement occurs simultaneously, the chance of error can be greatly reduced.

One further complication that may be encountered is the problem of the provitamin, of which carotene is a classical example with reference to vitamin A. Moore<sup>9</sup> and others have shown that crystalline carotene, although not in itself a vitamin, relieves vitamin A deficiencies and causes vitamin A to increase in concentration in the body fluids and in tissues like the liver. In the analysis of foodstuffs, therefore, the content of provitamin may be more significant than that of the vitamin itself. Nevertheless, in the body fluids or tissues, the vitamin is ordinarily the important form in relation to deficiency disease.

#### VITAMIN A

Although the existence of vitamin A has been known for many years and its relation to carotene studied carefully, practical methods for the quantitative determination of this vitamin in human blood are only in a preliminary stage. The detection of vitamin A deficiency by the use of biophotometers for night blindness, or hemeralopia, has had a vogue in recent years, but it has become apparent that this method is fraught with many complications. Accordingly, investigators are turning back to the direct measurement of vitamin A in serum or plasma to determine a deficiency of this vitamin. In general, the tests are based on two optical procedures: the colorimetric and the spectrometric.

The first of these utilizes the classic Price-Carr blue reaction, which the vitamin gives with antimony trichloride under certain conditions. The difficulty is that this color is evanescent and is not altogether specific for vitamin A. Some of the difficulties involved have been summarized by Lindqvist.<sup>10</sup> Because of these obstacles, Munsell<sup>11</sup> thinks that the spectrometric method of analysis holds more promise. Nevertheless, by the use of the photoelectric colorimeter or a step-photometer, it has been possible already to analyze the plasma or serum of the blood under different conditions. The results are apparently consistent within themselves, although there is a considerable difficulty in any investigation in converting the values given back into absolute terms.

Accordingly, at present, many clinical values are merely stated in "blue units" to indicate that the conversion factor of these units in actual concentrations is a matter of conjecture. Nevertheless, as reported by Pett and LePage,<sup>12</sup> within four hours after the ingestion of 20,000 international units of vitamin A, the plasma "blue unit" value rose from 76 to 133 international units. The rise indicated that about 10 per cent of the vitamin administered was in the circulation. The authors found that 88.0 microgm. of beta-carotene gave the same blue color as 84.1 international units of vitamin A. Accordingly, some method of correction must be made for the carotene test. The carotene, however, can be determined by other methods, the simplest of which makes use of the characteristic yellow color of this substance.

In his comprehensive monograph on the absorption, metabolism and storage of vitamin A and carotene, With<sup>13</sup> has discussed the behavior of these absorptive bands toward ultraviolet light from the standpoint of routine analytical procedures. He emphasizes the great variation in the conversion factors found by independent investigators. The same author has also collected many valuable data on the metabolism of these two related substances. He points out that normal subjects most frequently show a serum carotenoid concentration of between 20 and 50 microgm. per 100 cc. Values over 100 microgm. are rare. In the blood from the umbilical cord, however, values of about 10 microgm. are ordinarily found. The carotene content of serum, expressed as percentage of the total carotenoid, is highly variable. It ranges from one tenth to one half of the total.

Only rarely does vitamin A pass through the kidney into the urine. Pregnancy may be an exception; likewise, the urine may contain vitamin A in cases of infectious disease, liver lesions, malignant tumors and diabetic acidosis. In such cases, perhaps, it is combined with abnormal excretory substances.

Tolerance tests give, as they are applied at present, no information about the carotenoid or vitamin content of the organism.

The photometric technic has been applied in a number of interesting clinical conditions. For example, May and McCreary<sup>14</sup> have used a photometric method reported by Dann and Evelyn<sup>15</sup> to determine the vitamin A content of serum in celiac disease. Clausen and McCoord,<sup>16</sup> using a similar method, found that the mean vitamin A was 20.2 U.S.P. units per 100 cc. of plasma; the standard deviation was 10 units. Pett and LePage<sup>12</sup> obtained values in relatively normal subjects ranging from 50 to 90 international units per 100 cc. of plasma. These data showed a good correlation with visual tests. In natives of Batavia suffering

from xerophthalmia, deHaas and Meulemans<sup>17</sup> observed no more than a trace of vitamin A in the serum. Similarly, Clausen and McCoord<sup>16</sup> found that infection caused a prompt fall in the concentration of carotene and vitamin A in the plasma. Similar studies have been made by Wilbur<sup>18</sup> in adults and by May, Blackfan, McCreary and Allen<sup>19</sup> in children.

Somewhat paradoxical results have been found in diseases that involve disturbances of lipid metabolism. For example, in hypothyroidism, the content of the plasma may be low in vitamin A, returning to normal after thyroid therapy. In Bright's disease, however, the level may be greatly elevated. This observation is consistent with the effects noted by Josephs,<sup>20</sup> who made correlative studies of the blood levels of vitamin A, carotene, cholesterol and blood fat. He concluded that there is a direct relation between vitamin A, carotene and the total lipids of the blood. Indeed, the highest carotene and vitamin A values in his series were found in conditions associated with lipemia, that is, hypothyroidism, nephrosis and xanthomatosis. His lowest values were obtained in infants with pneumonia, and in patients with cardiac decompensation or with evidence of other deficiencies. In cases of pneumonia with low values for vitamin A, low values for total lipids were also found. This was true also of the cardiac cases, but not in cases of dietary deficiencies.

Of special interest is the finding by Abels, Gorham, Pack and Rhoads<sup>21</sup> of low levels of plasma vitamin A in patients with cancer of the gastrointestinal tract. Their results may be related to studies of cirrhosis of the liver by Ralli, Bauman and Roberts.<sup>22</sup>

In summary, it may be said that with the introduction of more precise optical apparatus, such as the spectrophotometer, there is a high likelihood that relative values for vitamin A and for carotene will be available and that such values will have a very important pathognomonic significance. It will be difficult to have absolute accuracy, but this goal is not beyond expectation in the near future. Such methods bid fair to supersede the visual tests as measures of vitamin A deficiency. At the present time, however, it must be admitted that this field is just being developed by clinical investigators.

#### THIAMIN (VITAMIN B<sub>1</sub>)

Several methods applicable on a clinical scale have been proposed for the estimation of thiamin. Notable among these are two that involve the use of micro-organisms. For example, Light, Schultz, Atkin and Cracas<sup>23</sup> used a fermentation test for vitamin B<sub>1</sub> that is applicable to many prob-

lems.<sup>24, 25</sup> Likewise, the growth of phycomyces has been applied by Schopfer<sup>26</sup> and Meiklejohn.<sup>27</sup> More convenient, however, are chemical procedures, notably the thiochrome assay of Jansen<sup>28</sup> and the test of Prebluda and McCollum.<sup>29</sup>

In the latter method, which has been applied extensively by Melnick and Field,<sup>30</sup> the urine or other material to be analyzed is first extracted with benzyl alcohol. The reaction between the vitamin and diazotized para-aminoacetophenone, described by Melnick and Field,<sup>31</sup> is the basis for the determination. This method is highly accurate and specific, but the technic is rather complex for ordinary clinical purposes. In general, I prefer tests based on the thiochrome conversion of Jansen, the principle of which is the oxidation of thiamin to thiochrome by an appropriate amount of ferricyanide in strongly alkaline solution. Jansen has shown that a quantitative, although not complete, conversion into thiochrome occurs under appropriate conditions. Thiochrome has the property of fluorescing as an intense blue color in ultraviolet light. The intensity of the fluorescence depends on the amount of thiochrome present. This may be measured either with a photoelectric cell or by direct visual comparison with a series of standard tubes.

The technic of this reaction has recently been surveyed by Egaña and Meiklejohn,<sup>32</sup> who point out that a preliminary extraction with isobutyl alcohol removes many interfering substances. The technic is complicated somewhat by the fact that certain interfering substances in pathologic urine hinder the recovery of the thiamin as thiochrome and so tend to exaggerate a paucity of the vitamin in urine from patients exhibiting profound disturbance of metabolism. Nevertheless, this method is now properly adapted for clinical observation. For a normal subject placed on a low thiamin diet, Egaña and Meiklejohn have found that in the course of a fortnight the twenty-four-hour excretion of the vitamin decreases from over 100 microgm. daily to less than 10. At this point, the urine is obviously pathologic. It may contain albumin, casts or blood, and certain chemical substances probably related to porphyrins or to indoxyl.

In my laboratory a twenty-four-hour urinary excretion of less than 70 microgm. of thiamin, as determined by the thiochrome method,<sup>32</sup> is considered *prima-facie* evidence of undoubted deficiency. Possibly this arbitrary value should be higher for men.

It is impossible to discuss the physiology of thiamin metabolism in this article, but a few illustrative results may be cited to indicate how the method may be applied clinically. Westenbrink

and Goudsmit<sup>33</sup> found that the urinary excretion of the vitamin depended on the amount injected. On a deficient diet, the urinary excretion decreased to a low level within three days. Likewise, Jowett<sup>34</sup> studied fractional urinary excretion following the administration of a known amount of vitamin. In normal subjects, the excretion for twenty-four hours varied from 80 to 300 microgm., and the great majority of cases showed over 100 microgm. for twenty-four hours' urine. When 3 to 5 mg. of pure thiamin was administered by mouth, the urine increased in concentration within the first hour after the administration, reached a peak between the second and fourth hours, and approached the normal level in about five hours. When larger doses were given, the increased excretion might extend into the second day. Furthermore, the percentage excreted depended on the size of individual doses rather than on the total dose given a day. It is interesting that intramuscular injections gave a maximal excretion during the first hour, and thereafter an excretion corresponding to that following oral administration. Curiously enough, these parenteral test doses disclosed no difference between normal and thiamin-deficient subjects, and the parenteral method was therefore considered to be of little value in differentiating normal persons from those suffering from lack of the vitamin. Pregnancy decreased the excretion of the vitamin, even in the absence of demonstrable clinical vitamin deficiency.

Obviously, the activity of the gastrointestinal tract modifies these responses considerably. Thus, Ritsert<sup>35, 36</sup> found a high fecal excretion amounting to 100 to 400 microgm. of thiamin in twenty-four hours in normal men. Indeed, after a single 10-mg. dose of thiamin, only about 5 per cent was found in the urine, whereas over 20 per cent was found in the feces. Obviously, much thiamin was not absorbed. Other factors no doubt enter into the picture. For example, Melnick, Field and Robinson<sup>37</sup> have found that vitamin B<sub>1</sub> is unstable in alkali and that, at the alkalinity of the small intestine, thiamin is slowly destroyed. In patients with ulcerative colitis and diarrhea, absorption is also poor.

The oral thiamin-tolerance test has been made use of by several investigators. Among these, Borson,<sup>38</sup> Melnick, Field and Robinson,<sup>37</sup> Westenbrink and Goudsmit<sup>33</sup> and Jowett<sup>34</sup> have reported interesting results. If gastrointestinal disease can be excluded, it is assumed that the recovery in the urine represents a measure of the degree of unsaturation of the patient's tissues. Accordingly, the percentage excreted is inversely proportional to the size of the dose given by mouth. The extent of the deficiency may be estimated in two ways:

either by determination of the number of daily doses required for the excretion to rise to normal, or by observation of the amount failing to be excreted after a single large dose. In this way, Westenbrink and Goudsmit found that the urine normally contains over 100 microgm. a day. When 3 to 5 mg. of thiamin is given,—preferably with a morning meal,—urinary excretion is increased in one hour, reaches a peak at about three hours, and returns to normal at five hours. Occasionally, doses as large as 100 mg. are given to patients, but probably over 90 per cent of such a large dose fails to be absorbed or is destroyed in the intestine.

By these methods, definite deficiency may be detected in many chronic diseases, including thyrotoxicosis, multiple sclerosis, neuritides of various types, central-nervous-system syphilis and certain neurasthenias. Ulcerative colitis likewise tends to show a low excretion. In normal pregnancy, the urinary excretion tends to fall, even in the absence of disease or true deficiency. Furthermore, in this laboratory, Dr. R. C. Roskelley<sup>39</sup> has found that a considerable percentage of cancer patients show thiamin deficiency even though they may present a clinical appearance of fair nutrition.

An approximate conception of this difference between the composite thiamin-tolerance curves of 14 noncancerous and 10 cancerous patients may be formulated by plotting against the time in hours (abscissa) the rate of urinary thiamin excretion in micrograms per hour (ordinate). The following abscissas should be plotted for time (hours): 0, 2, 3, 4, 5, 6, 8 and 24. The corresponding ordinates for noncancerous persons are 4, 72, 226 (peak), 95, 88, 53, 16 and 10. The corresponding ordinates for cancerous patients are 7, 26, 46 (peak), 32, 27, 24, 14 and 9. When these two composite curves are plotted, the striking difference in their respective heights will be apparent at once. It should be noted that these curves were obtained by the feeding of 5 mg. of thiamin with a meal, usually breakfast.

Of course, many cancerous patients encountered in a general clinic suffer from thiamin deficiency per se, as evidenced by a preliminary thiamin excretion of less than 70 microgm. per twenty-four hours. Obviously, such patients show a low tolerance curve. The data summarized in the preceding paragraph, however, were derived from patients whose preliminary thiamin excretion was in all cases greater than 70 microgm. per twenty-four hours; therefore, the flat curve for cancerous persons is especially interesting and merits careful investigation of the mechanism involved.

Similarly, O'Shea-Elsom and Machella,<sup>40</sup> in a study of vitamin retention in patients with hepatic cirrhosis, found some diminution in the excretion

of extra thiamin. The cause of this, however, they attributed to faulty absorption.

### Blood Thiamin

It is interesting that under normal conditions very little pure thiamin is found in the blood, in either the cells or the plasma. Indeed, the plasma seems devoid, or nearly so, of any thiamin derivative. The red cells, however, contain definite amounts of the enzyme cocarboxylase, which was first identified chemically as thiamin-pyrophosphate by Lohmann and Schuster.<sup>41</sup> Even after the administration of thiamin chloride by vein, in the course of ten minutes to an hour, the material disappears from the plasma. This is true because much of the vitamin escapes into the urine, and also because it is converted in large measure into cocarboxylase. Simultaneously, there is a rise in the cocarboxylase content of the red cells. Methods are available for estimating this cocarboxylase concentration,<sup>42</sup> but as yet they have not been applied extensively to clinical patients.

In a procedure recently developed by Egaña,<sup>43</sup> the blood diphosphothiamin and the thiamin itself are determined after separate conversion into thiochrome. In normal persons, Egaña finds that the diphosphothiamin level in whole blood is 7.0 to 8.5 microgm. per 100 cc. He finds no coenzyme in the plasma. The free thiamin reaches a concentration of 3.5 to 4.2 microgm. per 100 cc. of whole blood, and is present in both cells and plasma.\*

### RIBOFLAVIN (VITAMIN B<sub>2</sub>)

Riboflavin possesses several characteristic properties that are useful in its estimation. For example, Kuhn, György and Wagner-Jauregg<sup>44</sup> demonstrated that pure riboflavin gives off a yellow-green fluorescence on activation by light of certain wave lengths. This property has been used extensively in the estimation of the vitamin. It is also possible, as shown by Koschara,<sup>45</sup> to measure the vitamin concentration by the direct measurement of its color or light absorption. This method, however, has found less favor than the fluorescent one, in which the final concentration of the vitamin is determined either by comparison with a direct series of standards under monochromatic ultraviolet light or, more effectively, by the use of a fluorophotometer. Because riboflavin is sensitive to light, it is essential that examination of the vitamin be carried out under controlled illumination. Various procedures have

been used in the preparation of the final filtrate for the determination. Indeed, the vitamin has been measured by its color, by the use of a spectrophotometer, by its fluorescence in aqueous solutions, by the color of its derivative, lumiflavin, dissolved in chloroform, and by the polarograph method. Most of these involve preliminary extraction of the vitamin. Najjar<sup>46</sup> has described one of the more useful of these procedures. He adds pyridine to the urine or other aqueous medium under investigation, and then separates the pyridine by salting out with anhydrous sodium sulfate. The separating pyridine contains practically all the riboflavin. Ultimately, the vitamin is extracted into butyl alcohol and measured in a fluorophotometer illuminated by a mercury-vapor bulb.

Likewise, Hodson and Norris<sup>47</sup> extracted the riboflavin in 0.25 normal sulfuric acid, and subsequently subjected the solution to treatment with sodium hyposulfite and stannous chloride at pH 7.

After a suitable extract is made, it is usually necessary to remove the vitamin selectively by adsorption. Accordingly, Ferrebee<sup>48</sup> introduced two preparations of fuller's earth, known as Floradine and Supersorb, respectively. Elution from these adsorbants was accomplished with a solution of 20 per cent pyridine in 2 per cent acetic acid. Even at this stage, however, the filtrate contains pigments that interfere with optical measurements. To remove such interfering substances, the eluate may be treated with an oxidizing agent, for example, potassium permanganate or hydrogen peroxide. A convenient modification of these methods that combines the determination of riboflavin and thiamin in food products has been described by Conner and Straub.<sup>49</sup> The riboflavin content of the solution is determined as follows:

After elution of the uroflavin and subsequent oxidation to decolorize the solution, the solution is made up to volume with water, and the fluorescence measured with an exciting mercury-line beam at 4358 angstroms. The fluorometric photoelectric cells should be protected by a filter, described by Conner and Straub.<sup>49</sup> Turbidity of the solution or a gaseous emulsion must not be present. Under these circumstances, the relation between the fluorescence and riboflavin concentration is a linear one when suitable corrections are made for optical densities.

The urines of normal subjects frequently contain more than half a microgram of flavin per cubic centimeter,<sup>50</sup> and under these circumstances the urine may be diluted to the point where salts and other materials present no longer affect the fluorescence, as shown by Kuhn and Moruzzi.<sup>51</sup> After interfering substances have been oxidized according to Koschara's<sup>45</sup> procedure, the fluorescence may be measured at once. When the urine is more dilute in vitamin, some preliminary con-

\*While this article was in press, there appeared two papers by Rhoads and his collaborators<sup>50, 51</sup> on the thiamin content of blood in leukemic patients. In this disturbance, the leukocytes and erythrocytes contain an abnormally high concentration of "combined thiamin." Consequently, the total thiamin content of the whole blood is approximately three times the normal. The ultimate significance of this important finding is not yet established. Certain cases of Hodgkin's disease and cancer of the gastrointestinal tract behave similarly.

centration of the uroflavin is necessary, such as that accomplished by the methods of Ferrebee<sup>48</sup> and of Conner and Straub,<sup>49</sup> already cited.

As a qualitative check for the presence of riboflavin, the uroflavin may be converted into lumiflavin by the action of light in cold, strongly alkaline solutions. Under these circumstances, a chloroform-soluble pigment that shows a faint green fluorescence is formed. This method is as yet in the early stages of development.

Henry, Houston and Kon<sup>52</sup> have compared the biologic method of assay of riboflavin with the fluorometric assay and have found good agreement in various milk products. So far as other methods of assay are concerned Arnold, Lipsius and Greene<sup>53</sup> have tested the microbiologic procedure of Snell and Strong,<sup>54</sup> which is based on the influence of this substance on the growth of *Lactobacillus casei*. This method is tolerably specific and much quicker than the rat-assay method, and can be carried out with very small amounts of material. The twenty-four-hour excretion of riboflavin in normal subjects varies from 700 to 1700 microgm. In general, as shown by Emmerie,<sup>55</sup> urinary excretion tends to follow the riboflavin content of the diet.

#### *Physiologic Role of Riboflavin*

It is known that riboflavin when phosphorylated, that is, when combined with phosphate, is utilized as the prosthetic group for several tissue-enzyme systems that are important in biologic oxidation. Some of these are described by Karrer et al.<sup>56</sup> Well-known metabolites, such as lactic acid, the  $\gamma$ -amino-acids and glucose, depend in part on this combined vitamin for their utilization in bodily economy. For these reasons, human illness can result from lack of the vitamin. As yet, however, no extensive study has been made of its clinical applications. Sebrell<sup>57</sup> calls attention to the prevalence of vitamin B<sub>2</sub> deficiency associated with other deficiencies, notably that of nicotinic acid. In these conditions, the relief of such lesions as the vascularization of the cornea and the healing of fissures of the mouth—the so-called “perleche”—often depend on the supply of vitamin B<sub>2</sub>. These lesions are not relieved by either thiamin or nicotinic acid. At the moment, however, no clear-cut clinical pathologic entity unaccompanied by manifestations of other vitamin deficiency is generally recognized as specifically requiring riboflavin for therapy without other vitamins. In the mixed vitamin deficiencies, fortunately, diets that contain thiamin or nicotinic acid usually supply adequate riboflavin.

Nevertheless, there are available certain interesting observations in man that will serve as a background for future clinical studies. For example, after the oral administration of some 200 mg. of riboflavin, Klein and Kohn<sup>58</sup> recovered about 25 per cent from the urine as riboflavin. At the same time, the dinucleotide concentration in the erythrocytes was approximately 30 microgm. per 100 cc. However, the actual concentration of the flavin-adenine dinucleotide in urine and saliva after such a large injection of riboflavin was less than 1 microgm. per 100 cc. Obviously, the dosage given in this case must be considered unusually high, because Cowgill<sup>59</sup> has estimated the daily requirement of riboflavin at from 1 to 2 mg. a day for an adult. Stiebling and Phipard<sup>60</sup> have confirmed this value.

#### *Blood versus Urinary Riboflavin*

Axelrod, Spies and Elvehjem<sup>61</sup> have found that in normal subjects blood riboflavin values range between 35 and 45 microgm. per 100 cc. Surprisingly enough, approximately the same blood values were found in a group of patients with riboflavin deficiency. Apparently, the determination of the riboflavin concentration in blood or muscle is of little significance in evaluating riboflavin deficiency in man. Accordingly, it is preferable to use urinary excretion. Thus, Strong, Feeney, Moore and Parsons<sup>62</sup> found that the daily urinary excretion of riboflavin by normal human adults was between 500 and 800 microgm. a day. When the dietary content of riboflavin was reduced to 1 or 2 mg. a day, the urinary value soon decreased to 50 to 150 microgm.

When 5 mg. daily was given supplementary to the diet, most of it was excreted promptly. However, in the presence of vitamin deficiency, no extra vitamin was excreted in response to the reinforcement of the diet, or else the response was small and delayed. Here again, one finds that the vitamin tolerance or vitamin retention, as with thiamin, is a better and more convenient index of vitamin lack than direct determinations in the blood.

Although much further clinical work needs to be done with this vitamin, it seems likely that tolerance tests for its lack are useful in obscure cases of ophthalmologic or dermatologic nature. It is also probable that such a test may be valuable in cases of vague neurologic or psychic disturbance. It remains to be seen what the status of this vitamin is in cancer. The work of Rhoads and his co-workers<sup>63, 64</sup> suggests that this vitamin may be implicated in cancer of the liver, if not in other malignant processes. To test this point, tolerance

tests involving riboflavin are being made in this laboratory by Dr. Roskelley. It is apparent that patients with cancer may suffer from such vitamin deficiency, but the implications of this fact are not yet clear.

(To be concluded)

### CASE 28161

#### PRESENTATION OF CASE

A thirty-five-year old clerical worker was admitted to the hospital because of abdominal enlargement.

Three years before entry, the patient, who had previously been quite well, began to have vague abdominal distention and sensations of epigastric illness after meals, relieved by soda. There were no other symptoms. After about two years, the distention and fullness became severer, and the patient began to lose appetite. He limited his diet to fruit and vegetables. Cough, productive of small amounts of mucoid sputum, next appeared. The patient consulted his physician, and was referred to a sanatorium. Physical examination at that time showed great enlargement of the spleen, the lower pole reaching to the level of the left iliac crest. A few moist rales were heard at the left apex. A large "hemangioma" involved the left hand, in the area of ulnar-nerve distribution. The blood showed a white cell count of 4700, with 54 per cent polymorphonuclears, 39 per cent lymphocytes, 1 per cent monocytes and 5 per cent eosinophils. The red cell count was 4,100,000, with 32 per cent hemoglobin. The icteric index was 50. The blood Hinton reaction was negative. The sputum was negative. A roentgenogram of the chest showed bilateral apical mottling, reaching to the second interspace on the right and to the third interspace on the left. A roentgenogram of the abdomen showed several large arcs of calcification in the lower portion. A roentgenogram of the left hand showed a rounded, laminated calcified nodule in the "hemangioma." A roentgenogram of the esophagus showed no evidence of varices. Two guinea pig inoculations of gastric washings were negative. The patient stayed in the sanatorium five months, and then left against advice, roentgenograms of the chest showing no regression of the mottling. A month later, he came to this hospital.

The past and family histories were irrelevant. There was no known exposure to tuberculosis. The patient had not been farther south than Washington, D. C.

On entry, the patient appeared well developed and nourished. The chest was flat, with somewhat limited expansion. Krong's isthmus was

narrowed to percussion on both sides, more on the left than on the right. No rales were heard. There was an area of increased breath sounds about 2 cm in diameter in the fourth left interspace, posteriorly. The lungs were otherwise normal. The heart was normal. The abdomen was soft, and the liver was not palpable. A large, firm, smooth mass lay in the left upper quadrant, extending halfway toward the midline and moving slightly on inspiration. There were no signs of free fluid. A soft swelling extended between the fourth and fifth fingers of the left hand, from palm to dorsum. A small, rounded, hard mass was palpable within this swelling.

The temperature, pulse and respirations were normal. The blood pressure was 100 systolic, 70 diastolic.

Examination of the blood showed a red cell count of 4,200,000 with 83 per cent hemoglobin, and a white cell count of 8000 with 79 per cent polymorphonuclears, 6 per cent lymphocytes, 14 per cent monocytes and 2 per cent basophils. No parasites were seen on smear. The red cells showed slight variation in shape. The serum protein was 9.4 gm per 100 cc, with an albumin-globulin ratio of 1.09. The nonprotein nitrogen was 20 mg. per 100 cc. The van den Bergh reaction was biphasic and slightly elevated. The urine was normal. A Congo red test showed 77 per cent retention. The tuberculin test was negative in a 1:10,000 dilution. The Frei test was negative. Gastric analysis showed 30 units of free acid half an hour after histamine.

A roentgenogram of the chest showed mottled increased density in both upper lung fields, with fine mottling in the left lower lung field. An apparent cavity was seen by fluoroscope in the right infraclavicular area. The heart was normal. The left diaphragm was slightly elevated and showed impaired motion. Roentgenograms of the upper gastrointestinal tract showed slight questionable dilatation of the folds of the lower esophagus. The otherwise normal stomach was displaced to the right by the greatly enlarged spleen. Multiple calcified mesenteric nodes were visible. Subsequent roentgenograms showed no evidence of a pulmonary cavity, and no evidence of esophageal varices.

On the seventh hospital day, peritoneoscopy was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. JACOB LERMAN: May we see the x-ray films?

DR. AUBREY O. HAMPTON: There are only one or two films of the esophagus that show the slightest suggestion of varices; all the rest are normal. I do not believe that the patient had any varices.

What appears to be the spleen comes to the crest of the ilium and displaces the stomach medially. The liver is 4 cm. above the right iliac crest, but the diaphragm is low on both sides, so that it is not a huge liver. Examination of the chest shows what appears to be tuberculosis in both upper lobes. There is mottled density on both sides and old pleurisy at the left base quite characteristic of tuberculosis. The questionable cavity disappeared in further examinations. The lower lobes are normal. The pathologic lesions are all in the upper lobes. Then we have a film of the hands; there is no pulmonary osteoarthropathy. The areas of calcification in the abdomen, these large round masses varying from 1 to 3 cm., have the appearance of tuberculous lymph nodes.

DR. LERMAN: The differential diagnosis centers about three important findings: splenomegaly, pulmonary disease, as indicated by the x-ray film, and "hemangioma" of the left hand, which was probably incidental. I shall consider the causes of enlargement of the spleen under three main headings: infections, tumors and miscellaneous factors.

Under the heading of infection, one must consider tuberculosis (tuberculoma) of the spleen as most likely in this case. This would explain the pulmonary picture and the calcified nodules in the abdomen referred to by Dr. Hampton. However, the absence of wasting, fever and other systemic symptoms is against this diagnosis. The failure to detect acid-fast organisms and the negative tuberculin reaction in a dilution of 1:10,000 argue strongly against tuberculosis but do not rule it out. I do not favor this diagnosis. Syphilitic gumma of the spleen must next be considered. The irrelevant history, absence of syphilitic disease elsewhere and negative blood Hinton reaction rule it out. Chronic malaria may give such a large spleen, but there was no history of malaria, and the blood smear was negative for malarial organisms. Finally, one should mention kala-azar as the cause of a large spleen. It need not be considered in this case because the patient had never been outside this country and the blood smears were negative for leishmania organisms. Of the diagnoses so far mentioned, only kala-azar would explain the high serum protein. This last finding also raises the possibility of lymphogranuloma inguinale, in which an elevated serum protein is common. The negative Frei test practically excludes this diagnosis.

So far as the possibility of tumor is concerned, hemangioma suggests itself as the most likely benign tumor because of the presence of hemangioma elsewhere. There is nothing to corroborate this diagnosis, which does not explain the pulmonary findings. Malignant tumors such as reticulum-cell sarcoma, lymphosarcoma, lymphoma and endo-

thelioma are unlikely because of the absence of systemic symptoms and of involvement elsewhere, considering the duration of the disease. A biopsy would be necessary for an absolute diagnosis. Chronic myelogenous leukemia is a frequent cause for such a large spleen. However, the absence of systemic symptoms, of severe anemia and of abnormal cells in the blood, as well as the high serum protein, excludes this disease. A cyst of the spleen is a possibility, but the description of the character of the spleen does not fit that of a cyst.

I must consider, in passing, the possibility of multiple myeloma, which is suggested by the high serum protein. There is nothing else in the description of the case that fits this diagnosis. Also worth mentioning are Gaucher's disease, hemolytic jaundice and thrombocytopenic purpura as causes of splenomegaly. There are no findings in this case to support any of these diagnoses.

There remain three diagnoses that fit this case best: amyloid disease, Banti's syndrome and sarcoid. The first two require an additional diagnosis to explain the pulmonary findings, whereas sarcoid accounts for both the splenomegaly and the pulmonary lesions.

Amyloid disease associated with pulmonary tuberculosis or nontuberculous pulmonary infection is a strong possibility. The absence of albuminuria, the high serum protein and the normal Congo-red test fail to corroborate it but do not rule it out. The enlargement of the liver mentioned by Dr. Hampton and the elevated van den Bergh reaction suggest liver involvement consistent with amyloid disease. In the early stages of this disease, there may be a high serum protein, with increased amounts of globulin.

Under Banti's disease, or splenic-vein hypertension, I am including such conditions as portal cirrhosis with splenomegaly or splenomegaly ending in portal cirrhosis, splenic-vein thrombosis and another type of splenic-vein obstruction. The age, duration of symptoms, relative good health of the patient, slight normochromic anemia and slight leukopenia are consistent with the diagnosis. The evidence of slight liver involvement is also in favor. At times, a high serum protein with hyperglobulinemia may occur in the early stages of cirrhosis. The absence of gastric bleeding is strongly against Banti's disease. Esophageal varices have played hide-and-seek with us. The failure to find them also argues against this diagnosis. Furthermore, the presence of an associated pulmonary infection, tuberculous or nontuberculous, must be assumed, to explain the findings in the lungs.

Sarcoid would explain the large spleen, together with the signs in the lungs, although the signs are not typical. The cases that I have seen have

shown involvement around the hilar regions, with areas of increased density radiating to the lower lung fields. Moreover, the spleen is unusually large for sarcoid, which may, however, be of this size. The elevated serum protein and the hyperglobulinemia are characteristic of sarcoid. The absence of skin, lymph-node and bone involvement argues against sarcoid but does not rule it out.

Of these diagnoses, I believe sarcoid is the most likely. The other possibilities are amyloid disease and Banti's disease, associated with pulmonary tuberculosis or nontuberculous pulmonary infection.

DR. HAMPTON. I think that would be a very unusual picture for sarcoid in the chest. I do not believe that we have seen localization of the pulmonary lesion to that extent in sarcoid.

DR. LERMAN: I agree; I mentioned the fact that it is unusual for sarcoid. The lesions are usually lower and around the hilum.

DR. DONALD S. KING: Or diffuse through both lungs. We advised peritoneoscopy on this patient because he was much like the one of Dr. Robert S. Palmer's patients who was operated on for a large spleen and who had an x-ray film a good deal like this. But this lung does have lesions down toward the base.

DR. HAMPTON: A spleen as large as that in sarcoid must be rare.

DR. TRACY B. MALLORY: We have had two sarcoid spleens weighing approximately 1000 gm.

DR. LERMAN: There are cases in the literature in which splenectomy was done.

DR. KING: Dr. Palmer's case looked like milary tuberculosis. They took the spleen out at operation, thinking that it was milary tuberculosis.

DR. MALLORY: Dr. Benedict, do you want to tell about the peritoneoscopy?

DR. EDWARD B. BENEDICT: The liver showed multiple fine, gray, linear markings, and the spleen showed pin-point gray markings on the surface, high above the splenic notch. The spleen was enlarged to the umbilicus. The liver did not appear very large. This slide shows the appearance of the liver.

DR. MALLORY: I am quite sure if I saw the surface of the liver looking like that I should have no idea what it was.

DR. BENEDICT: This is the artist's interpretation, and I think it is accurate. I called Dr. Castleman to look at it, and as a matter of fact he said it was consistent with what the diagnosis was.

DR. MALLORY: That was a good guess.

#### CLINICAL DIAGNOSES

Splenomegaly and pulmonary pathology.  
Sarcoid?

#### DR. LERMAN'S DIAGNOSIS

Sarcoid

#### ANATOMICAL DIAGNOSIS

Sarcoid.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY. Dr. Benedict removed a small piece of the liver, sections of which showed considerable fibrosis, but no signs of caseation; it seemed to us typical of sarcoid. We have a little further confirmatory evidence. This patient was kept on the wards some weeks without much change, allowed to go home, told to rest as much as possible and to keep on a high vitamin diet and so forth. Shortly after his return home, he developed some peculiar gastric symptoms, with almost constant nausea, and came back to the hospital again. Studies were made that offered no explanation for the symptoms. Both x-ray examination and gastroscopy were essentially negative, although I think that Dr. Benedict reported a little superficial gastritis. After a few weeks, this quieted down; the patient was again discharged and has been seen at monthly intervals up to last September. During this last period he has grown progressively better and, when last seen, expected to go back to work in a couple of days. On one entity, it was noted that he had a rather granular conjunctivitis, and a biopsy likewise showed typical sarcoid. So that we have two biopsies showing the same thing.

DR. ALFRED KRANES: Did the enlarged spleen disappear?

DR. MALLORY: There was no note on the last occasion about the spleen. It stayed large for a long time, I am sure.

DR. HAMPTON: I think that this film was taken a month later. The chest appears normal, or practically normal. It has cleared up somewhat.

DR. ALLAN M. BUTLER: Is there any comment regarding therapy for this case?

DR. KING: Symptomatic treatment is all that one can do. The disease will clear up almost always without any therapy.

#### CASE 28162

#### PRESENTATION OF CASE

A sixty-year old Swedish watchmaker was admitted to the hospital because of diarrhea.

The patient was quite well until about two years before entry, when he began to have bouts of diarrhea. Each episode lasted three or four days, during which from five to seven urgent watery movements occurred daily. The diarrhea alternated with periods of three to five days of normal bowel movements. The patient was never constipated. On occasion, the stools were foul smelling and included mucus, but no blood was

ever noted. In the first year of the illness, the patient consulted two physicians, and was given various pills and medicines. A year before entry, following an upper respiratory infection, he began to cough up small amounts of thick sputum. He had no chest pain, and the sputum contained no blood. The cough abated appreciably after several days of bed rest, but never went away entirely. At about this time, the patient became aware of a small left inguinal hernia, which persisted. In the year before entry, the diarrhea became more frequent and severer. Occasionally, movements occurred at night. In this last year, a gnawing epigastric pain also appeared, gradually becoming worse. This pain was sometimes accompanied by cramping pain in the lower abdomen, followed by an episode of diarrhea. Occasionally, food relieved the epigastric pain, but otherwise there was no relation between the pain and meals. At times, the pain came on at night, when it radiated to the lumbar region. Throughout the illness, there was insidious progression of weakness and fatigability, and a loss of 36 pounds in weight.

On admission, the patient appeared large, powerfully built, fairly well nourished and in no acute distress. The skin was pale. The axillary and inguinal lymph nodes were shotty. The lungs were clear. The heart was not remarkable. The abdomen showed diastasis of the rectus muscles in the epigastric region. An indefinite, firm, tennis-ball-sized mass was palpable in the right upper quadrant, moving on respiration. A small, reducible indirect hernia was present in the left inguinal region. A firm, moderately hypertrophied prostate was palpable by rectum.

The blood pressure, pulse, temperature and respirations were normal.

Examination of the blood showed a red-cell count of 3,800,000 with 8.5 gm. hemoglobin, and a white-cell count of 18,300 with 66 per cent polymorphonuclears. The urine showed a trace of sugar. The stools were liquid brown and guaiac negative. Stool culture was negative for pathogens. The serum protein was 4.9 gm. per 100 cc.

Roentgenograms of the large bowel showed a ready flow of barium through the rectum and sigmoid to a point in the midtransverse colon beyond which the barium would not pass. At this level, there was a constant filling defect, with a scalloped, irregular polypoid margin. The folds of the mucosa appeared markedly thickened for a distance of 5 cm. beyond this place. In another examination, barium flowed readily through the sigmoid and transverse colon to outline a cone-shaped narrowing in the region of the hepatic flexure. There were two nodular filling defects at the proximal end of the area of obstruction.

Apparent mucosal markings remained in the area of narrowing, arranged in concentric rings at the distal widest point. A roentgenogram of the chest showed no evidence of disease.

On the tenth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. ALLEN G. BRAILEY: This history presents a classic example of slowly developing obstruction of the large bowel. The exact mechanism of such recurrent bouts of diarrhea is not known but it is likely that the irritation of the obstructing lesion, in addition to the irritation of fecal material behind the obstruction, produces an increase of tonus of the muscular wall and more and more vigorous peristalsis, until finally the obstruction is overcome. The abnormally vigorous peristalsis then results in diarrhea, just as it does when produced by any other cause. After the bowel is emptied, a period of rest ensues until the accumulated bowel contents start the cycle over again. The bouts of diarrhea occurred at ever-shortening intervals, and the muscular activity of the bowel proximal to the obstruction became more and more vigorous until actual colicky pain appeared. Nothing is said about loss of appetite, but we know that such an interference with normal intestinal motility invariably results in anorexia, and this is borne out by the fact that the patient was reported to have lost 36 pounds in weight. The malnutrition that resulted from the anorexia probably accounted for his weakness and fatigability, his anemia and his lowered serum protein, although there may have been other causes for these impairments of health.

This train of events was set off by an obstructive lesion of the midtransverse colon whose x-ray description is somewhat unusual. Have you anything further to say about that, Dr. Hampton?

DR. AUBREY O. HAMPTON: I remember the film very well, and I know the answer. The conical defect with multiple small, round, filling defects in the transverse colon was definitely unusual. We did not demonstrate the whole lesion, because we could not get barium beyond the point of obstruction, but the distal margin did not show the usual picture of carcinoma. It had too many fine, irregular projections from it.

DR. BRAILEY: Was there evidence of polyps anywhere else?

DR. HAMPTON: There were no other polyps. These polyp-appearing things were all grouped together in one spot, but we could not tell whether they were continuous or not.

DR. BRAILEY: Do you think that the mucosa was normal? It was not destroyed?

DR. HAMPTON: In the area near the polypoid

fects, it was normal, but toward the obstruction it was lost in a mass of polypoid defects.

DR. BRAILEY: Our first problem is to decide whether this was a lesion that began in the mucosa or whether it was intramural in origin. The statement is made that "the stools were liquid brown and guaiac negative." If the stools were persistently guaiac negative, they provide evidence of great importance in deciding the nature of this lesion. How many stools were examined?

DR. TRACY B. MALLORY: One stool was examined. The other stool was cultured but not tested for guaiac.

DR. BRAILEY: That is too bad. I presume one might have an occasional stool with a negative guaiac reaction, but certainly it is very rare in carcinoma that has developed to the point of obstruction. The mucosa is destroyed, and oozing must occur.

I assume that this observation can be trusted, and we can therefore exclude practically any lesion, such as carcinoma, that arose in the mucosa or destroyed the mucosa, for all such lesions ooze blood and most if not all the stools would show the presence of occult blood. If I do not lose my courage and am consistent with this line of reasoning, the lesion developed within the wall of the bowel. It might have been tuberculosis. Although the x-ray appearance was not very suggestive of tuberculosis, I do not believe that this rules it out. On the other hand, tuberculosis almost invariably involves the mucosa with ulceration at an early stage; it very rarely develops in a man of this age who has no evidence of tuberculosis in the chest, and I therefore discard tuberculosis as a likely possibility. I believe that it is much more probable that this man had a new growth as the cause of his obstruction. If we must exclude primary carcinoma for lack of bleeding, we are left with metastatic tumor, which is too unlikely to be considered further, and with the various sarcomas that may develop from bowel-wall structures. These include leiomyosarcoma, angiosarcoma, sarcomas arising from nerve tissue and various types of lymphoblastoma. It is obvious that this man required an operation. It is also clear that a final diagnosis could not be made without pathological study. However, I think that lymphosarcoma is the best bet.

DR. CHESTER M. JONES: I should like to disagree with Dr. Brailey. We have been surprised at the number of patients with carcinoma of the stomach and bowel who for days on end have had guaiac-negative stools. No diagnostic inference can be placed on that, even if it were correct. Dr. Hampton points out that the relatively low red-cell count suggests that the stool report was

not correct. Even if the anemia were based on malnutrition, it does not to my mind rule out cancer in any way.

It is a bit interesting to know the cause of the epigastric pain. The patient had two sets of symptoms. One set appeared quite late, and one had persisted for two years.

DR. WYMAN RICHARDSON: May I add to that statement the fact that the patient had not only a red-cell count of 3,800,000 but a hemoglobin of 8.5 gm. This means that he had a very severe hypochromic anemia, which further means he had lost blood from his bowel no matter whether the stools were guaiac negative or not. There is no question that this lesion had been bleeding—if these figures are correct, I hasten to add.

DR. BRAILEY: I started out with the assumption that there was no bleeding, but certainly with only one stool recorded I cannot maintain that argument. If we concede the bleeding, I should put my money on carcinoma rather than anything else.

DR. HAMPTON: We presented the case in our conference; I have forgotten the whole discussion, but I do not remember seeing a carcinoma with obstruction of this appearance, with these multiple, small, rounded defects as though there were many polyps in one place in the bowel—a picture of local polyposis, which I have never heard of, and at the same time a conical obstruction instead of a transverse, circular one. I do not know what our conclusions were, but I am interested in knowing what the histology is going to be.

DR. MALLORY: On the x-ray report, it was stated, "Probably carcinoma, but might well be lymphoma."

DR. HAMPTON: I think we hedged quite a bit; I should do so.

DR. JACOB LERMAN: Was there no comment about the mass that moved on respiration? If it was in the colon, it certainly would not move on respiration.

DR. HAMPTON: I disagree—the colon does move with respiration.

DR. BRAILEY: I am interested in Dr. Jones's comment that in frankly ulcerative carcinoma one can have repeated stools without blood in them.

DR. JONES: I did not say exactly that. I said that patients with cancer of the stomach or intestine—not, frankly ulcerative cancer—may go from days to weeks with no blood in the stools.

DR. BRAILEY: When the lesion is large enough to obstruct the bowel?

DR. JONES: I should not hedge on it a bit.

DR. CLAUDE E. WELCH: The Medical Department told us that this man had cancer of the colon. We did not see any reason to doubt the diagnosis and operated, with a two-stage resection. At the time of the ileocolostomy, a huge mass was located directly over the duodenum. The patient survived the first stage, and about two weeks later a resection was done. At that time, we observed considerable fixation of the mass posteriorly. It was hoped that this might turn out to be inflammatory. By the end of the resection, however, it was evident that there was considerable extension of the disease into the pancreas and that the wall of the duodenum was involved; a few nodules were found on the stomach. The main mass was taken out, but we knew we had left tumor behind.

#### CLINICAL DIAGNOSIS

Carcinoma of colon.

#### DR. BRAILEY'S DIAGNOSIS

Lymphosarcoma of colon.

#### ANATOMICAL DIAGNOSIS

Carcinoma of colon.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The specimen showed a very extensive carcinoma of quite low-grade malignancy. It involved 12 cm. of the bowel. Above the mass, the mucosa was very markedly edematous,—in fact, in some places more than 1.5 cm. in thickness,—but that could not explain the x-ray findings because the radiologists never saw the proximal side of the lesion. There were numerous polypoid tumor excrescences along the distal margin of the tumor, which I suppose they saw.

DR. HAMPTON: I saw the specimen, and I thought there were some fairly long mosslike strands of carcinoma protruding from the margins that probably floated in the barium.

## ELECTEES AND THEIR PHYSICAL FITNESS

The successful waging of any war depends on many factors. One of the more important is the physical fitness of the combat personnel. Much has been said concerning the health of the young men of this country, and there seems to be a rather general belief that they are strong and healthy. It has been claimed that the United States is a nation of athletes. But to be athletic does not necessarily imply that one can come up to the physical standards of the Army of the United States or the United States Navy. One well known professional football player was recently rejected by the Army for malignant hypertension. Furthermore,

two decades ago, a noted collegiate football player successfully represented one of the large universities for four years, even though he was known to have a high grade mitral stenosis, which was proved at autopsy a few years later. In the same era, one of the country's most renowned fencers had had infantile paralysis in early childhood.

Adequate and authoritative figures concerning the health of the Nation so far as the armed forces are concerned have heretofore been difficult to obtain, and it should be remembered that a really true picture can be had only from the collective data obtained from the selective service boards, the Army induction centers and the certificates of disability discharge after induction, with the exception, of course, of those discharges due to injuries in line of duty.

A preliminary survey<sup>1</sup> covering the first two types of examination is now at hand. It is illuminating but not encouraging. Fifty per cent of the approximately 2,000,000 registrants who were examined prior to May 31, 1941, were found unqualified for general military service by selective-service boards and Army induction centers because of physical, mental or educational defects or a combination of these. Twenty five per cent were considered unsuitable for any type of military service. The requirements for the Army and Navy are rigid, but certainly not unduly so. That roughly half our young men should be unsuited for military service does not reflect too well on the state of health of the Nation, and it should be remembered that this survey took no account of the hundreds of discharges for physical or mental handicaps that were missed during the preliminary examinations and that came to light only after a few weeks or months in camp.

Nor does one gain much solace from the breakdown of the figures. "Based on the major defect or principal cause of rejection, dental defects account for . . . 20.9 per cent of the 900,000 registrants not qualified for general military service . . ." It is probable—indeed almost certain

DR. CLAUDE E. WELCH: The Medical Department told us that this man had cancer of the colon. We did not see any reason to doubt the diagnosis and operated, with a two-stage resection. At the time of the ileocolostomy, a huge mass was located directly over the duodenum. The patient survived the first stage, and about two weeks later a resection was done. At that time, we observed considerable fixation of the mass posteriorly. It was hoped that this might turn out to be inflammatory. By the end of the resection, however, it was evident that there was considerable extension of the disease into the pancreas and that the wall of the duodenum was involved; a few nodules were found on the stomach. The main mass was taken out, but we knew we had left tumor behind.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The specimen showed a very extensive carcinoma of quite low-grade malignancy. It involved 12 cm. of the bowel. Above the mass, the mucosa was very markedly edematous,—in fact, in some places more than 1.5 cm. in thickness,—but that could not explain the x-ray findings because the radiologists never saw the proximal side of the lesion. There were numerous polypoid tumor excrescences along the distal margin of the tumor, which I suppose they saw.

DR. HAMPTON: I saw the specimen, and I thought there were some fairly long mosslike strands of carcinoma protruding from the margins that probably floated in the barium.

## SELECTEES AND THEIR PHYSICAL FITNESS

THE successful waging of any war depends on many factors. One of the more important is the physical fitness of the combat personnel. Much has been said concerning the health of the young men of this country, and there seems to be a rather general belief that they are strong and healthy. It has been claimed that the United States is a nation of athletes. But to be athletic does not necessarily imply that one can come up to the physical standards of the Army of the United States or the United States Navy. One well-known professional football player was recently rejected by the Army for malignant hypertension. Furthermore,

two decades ago, a noted collegiate football player successfully represented one of the large universities for four years, even though he was known to have a high-grade mitral stenosis, which was proved at autopsy a few years later. In the same era, one of the country's most renowned fencers had had infantile paralysis in early childhood.

Adequate and authoritative figures concerning the health of the Nation so far as the armed forces are concerned have heretofore been difficult to obtain, and it should be remembered that a really true picture can be had only from the collective data obtained from the selective-service boards, the Army induction centers and the certificates of disability discharge after induction, with the exception, of course, of those discharges due to injuries in line of duty.

A preliminary survey<sup>1</sup> covering the first two types of examination is now at hand. It is illuminating but not encouraging. Fifty per cent of the approximately 2,000,000 registrants who were examined prior to May 31, 1941, were found unqualified for general military service by selective-service boards and Army induction centers because of physical, mental or educational defects or a combination of these. Twenty-five per cent were considered unsuitable for any type of military service. The requirements for the Army and Navy are rigid, but certainly not unduly so. That roughly half our young men should be unsuited for military service does not reflect too well on the state of health of the Nation, and it should be remembered that this survey took no account of the hundreds of discharges for physical or mental handicaps that were missed during the preliminary examinations and that came to light only after a few weeks or months in camp.

Nor does one gain much solace from the breakdown of the figures. "Based on the major defect or principal cause of rejection, dental defects account for . . . 20.9 per cent of the 900,000 registrants not qualified for general military service. . . ." It is probable—indeed almost certain

—that nearly all such defects can be remedied or could have been prevented; furthermore, it should be noted that these official figures do not substantiate a claim made before the Massachusetts Dental Society<sup>2</sup> that but 2 per cent of the registrants were not accepted because of dental defects. Next in order as causes for rejection came defects of the eyes and diseases of the cardiovascular system,—13 and 10 per cent, respectively,—and it is not likely that many of these disorders are remediable or were preventable. Then follow musculoskeletal defects, venereal diseases, mental or nervous disorders, hernias and defects of the ears and feet, each roughly 5 per cent. Diseases of the lungs, including tuberculosis, were a cause for rejection in but 2.9 per cent—a creditable figure, although it should be remembered that registrants of some states had no x-ray films taken prior to induction.

Exactly how many of these rejected men can be rehabilitated is impossible to say. The survey states, "Of the 900,000 who have been classed as available for limited military service or disqualified for military service, an estimated 200,000 can be completely physically rehabilitated for the performance of general military service." The President has charged the Selective Service System with such a rehabilitation program. It should be noted, however, that no provision has yet been made whereby the man enlisting can have remediable defects corrected if he voluntarily does not have the money to do so himself.

Three things seem clear: an appallingly large number of young men are unfit for military service; many of the nonremediable disqualifying defects could have been prevented; and rehabilitation should benefit not only the armed forces but the Nation as a whole—whether at peace or at war. It is to be hoped that the physicians, dentists and hospitals of this country will aid in the correction of these defects.

## AMERICAN INSTITUTE FOR PSYCHOANALYSIS

ORTHODOXY and the scientific attitude can scarcely be considered compatible. Earnestness in the desire to seek the truth and willingness to discard supposed facts when they cannot be substantiated must be the foundation for honest, progressive scientific work. A justifiable criticism of some psychoanalysts of the Freudian school or of some of the psychoanalytic societies is that they insist on the orthodoxy, the incontrovertible correctness, of Freud's fundamental concepts. Their zeal in supporting their master's teachings sometimes exceeds what Freud himself probably would have thought permissible. If a theory or a hypothesis is sound, it may be examined searchingly without danger to its validity and without embarrassment to its proponents. When the advocate of any thesis reacts antagonistically to a questioning analysis of the soundness of his doctrine, it is fair to doubt his fitness for scientific investigation.

Whether for personal reasons or because of an impersonal, objective interest in liberal, scientific progress, a number of the members of the New York Psychoanalytic Society last spring severed themselves from the society and established the American Institute for Psychoanalysis. According to a statement issued by them, they could no longer put up with what they termed the "dogmatism" of certain elements within the society, and they believed that the future of psychoanalysis and psychoanalytic education would be jeopardized if directed with an ex-cathedra attitude.

In the organization of the new institute, the plan is to teach psychoanalysis as "a young science, still in an experimental stage of its development, full of uncertainties, full of problems to which anything approaching final and conclusive answers is still to be sought."

The disagreements and wrangling within a particular society may be considered inevitable and healthy for the vitality of the organization. The schism here referred to may be of no general importance. Since it is well known, however, that there is a tendency in some psychoanalytic circles

to defend some of Freud's hypotheses with a bias of almost religious faith, it is well for the future of psychoanalysis if some of Freud's followers have enquiring minds. No really great teacher in medicine ever wanted investigation to go forward with the provision that the soundness of his own contributions was to remain eternally indisputable.

Freud was a man, not a deity, and he allowed himself the privilege of changing his mind. A relief that his observations and conclusions were unswervingly accurate denies human fallibility. Even in the scientific world, the power and influence of personality can be tremendous. Most men admire the attributes of leadership and superior intellect, and for many physicians who cannot accept the tenets of a theological system, the human need for security is somewhat satisfied if they think that they see ultimate truth in a supposedly scientific cloak. Combine this admiration and this need with suggestibility, which is present in all of us to more or less degree, and the critical faculty is not likely to be dominant. It is good to see that dissidence, even though possibly arising from personal resentment, may begin to break the spell of Freud's personality.

## MEDICAL EPONYM

### NIEMANN-PICK DISEASE

"Ein unbekanntes Krankheitsbild [An Unrecognized Syndrome]" was described by Dr. Albert Niemann (1880), assistant in the Berlin pediatric clinic of Professor Czerny, in the *Jahrbuch für Kinderheilkunde* (79: 1-10, 1914). A portion of the translation follows:

It is my present desire to direct the attention of my colleagues, particularly the pediatricists, to a very remarkable syndrome, which I speak of as unrecognized not only because I myself have never seen it before, but also because I have looked in vain throughout the literature for a description of it. . . .

The victim of the disease was a female child, aged seventeen months . . . who had been sick from the beginning of the second month of her life and whose chief symptom, even at that time, had apparently been a tumor, presumably of the spleen. . . .

We found a wretchedly nourished child, apathetic, underdeveloped, with wide-open fontanelles, unable to stand or walk. . . . The most striking finding on inspection was the tremendously enlarged abdomen (circumference, 50 cm.). This huge swelling consisted

of liver and spleen. The spleen extended far below the navel, as did the liver, the lower border of which was a fingerbreadth above the right anterior superior spine. The veins of the belly were markedly dilated, there was some demonstrable free fluid in the abdomen, and there were signs of congestion elsewhere: a catarrhal condition of the lungs, edema of the feet and eyelids. . . . There was no jaundice. . . . The congestive phenomena increased, diarrhea supervened, and finally after a stay of four weeks in the clinic, exitus occurred. . . .

Autopsy showed . . . a very large spleen, not excessively hard, with a rather spotted surface. Section revealed yellowish white foci, the size of a lentil, frequently confluent, between which only very narrow bands of normal splenic substance persisted, so that the cut surface looked whitish yellow when seen from a distance. . . . The liver was likewise markedly enlarged, with the color and markings of fatty degeneration such as that seen in cases of phosphorus poisoning. . . . The abdominal lymph nodes were not only moderately enlarged, but also showed a peculiar yellow fatlike color and were rather soft in consistence. . . .

Microscopic examination of the spleen showed . . . almost the whole structure to be replaced by peculiar cells . . . very large, irregular in shape, irregularly distributed, sometimes crowded together, sometimes separated from each other. They contained a small, round nucleus. . . . Exactly similar cells were found in the liver . . . and . . . also in the abdominal lymph nodes. . . . I should like to propose the name *groszzellige Drüsenmetamorphose* [large-cell glandular metamorphosis] for this disease.

Ludwig Pick (1868), director of the Pathological Anatomical Department of the Municipal Hospital, Friedrichsheim, Berlin, presented a communication, "Zur pathologischen Anatomie des Morbus Gaucher [On the Pathological Anatomy of Gaucher's Disease]," before the *Berliner medizinische Gesellschaft* on October 11, 1922. His remarks and the discussion that followed appear in the *Medizinische Klinik* (18: 1423 and 1449, 1922). A portion of the translation follows:

In a case of splenomegaly and hepatomegaly in a seventeen-month-old female child, described by Niemann in 1914 under the title "An Unrecognized Syndrome," the enlargement of the organs was due to an infiltration of lipid (phosphatid)-bearing cells, as Pick was able to show on subsequent examination of Niemann's material. This case, together with similar observations reported by Siegmund and American authors (Knox, Wahl and Schmeisser) belongs in a special group of lipid-cell splenohepatomegaly in children, in which the lipid cells are found in a considerable number of other organs (heart, dura, kidneys and so forth).

An exhaustive critique of the subject is given by Pick under the title "Der Morbus Gaucher und die ihm ähnlichen Erkrankungen [Gaucher's Disease and Similar Maladies]" in *Ergebnisse der inneren Medizin und Kinderheilkunde* (29: 519-627, 1926).

## CASE HISTORY: ACUTE INVERSION OF THE UTERUS, CAUSING HEMORRHAGE AND DEATH

A thirty-year-old multipara had had adequate prenatal care and was delivered at term of a living child. Labor, which had been induced for reasons not stated, lasted eleven hours and forty minutes. The delivery was a breech and was said to have offered no difficulty. The condition of the mother following delivery was satisfactory. The placenta was not delivered immediately, and Credé's method was resorted to, with the result that the uterus became acutely inverted. The placenta was peeled from the uterine wall. The bleeding was tremendous, and the patient's condition became grave. A tourniquet was placed about the inverted portion of the uterus, and the patient was given 750 cc. of whole blood. In spite of this, she died before the uterus had been replaced.

*Comment.* Inversion of the uterus is always a very serious complication. In this case, it was undoubtedly induced by undue attempts at Credé's method. That the placenta was still attached when the uterus became inverted is evidence that no separation had occurred before the procedure was attempted. Such attempts should never be made until there is evidence that the placenta has separated. Had this placenta been left, it is quite probable that it would have separated spontaneously and delivered itself without undue loss of blood. It is also probable that had this uterus been replaced under anesthesia as soon as it appeared at the vulva, the subsequent hemorrhage might have been averted. It is often impossible, however, to replace an inverted uterus manually. In such a case, laparotomy is indicated.

Cases of chronic inversion of the uterus are extremely rare, since most patients with uteri that become inverted and are not replaced die of hemorrhage. However, chronic inversion has been known to exist for months. For example, when one patient who had had several hemorrhages after delivery was finally seen in consultation about three months after her baby was born, a diagnosis of chronic inversion was made. She was operated on, the uterus was replaced, and the patient has since had a living child.

The fatality in the case presented seems to have been avoidable.

## "PROBLEMS OF TUBERCULOSIS UNDER WARTIME CONDITIONS"\*

Although tuberculosis is not popularly identified as one of the four horsemen of the Apocalypse, it is unquestionably one of the major pestilences of war; there is no more sensitive barometer of national privation and suffering. In World War I, the tuberculosis mortality in all combatant countries rose within the first year and climbed steadily until after the armistice. In France, England and Germany, the rates practically doubled, and even in this country the mortality in 1918 was 50 per cent higher than that in the preceding few years. In the United States, the total deaths from tuberculosis at least equaled the losses in battle in any year of the war.

Incomplete reports from Europe show that tuberculosis had again definitely increased in 1940, and preliminary data here indicate that nearly half the states experienced a slight rise in mortality in 1941. With the prospect of a war longer, more inclusive and far more exhausting than the last, it is high time that we define the problems of tuberculosis under wartime conditions and organize all available control measures in the civilian population as well as in the armed forces.

Essentially, the problems of control are the same in war and in peace: early recognition of cases, prompt hospitalization of those needing treatment, examination of family contacts, maintenance of adequate nutrition, good housing and a reasonable sense of security. The great problem is how to attain a semblance of such conditions with restricted food supplies in a situation that calls for the expenditure of the utmost effort of which we are capable.

The first line of defense is the maintenance, at all costs, of the very effective control organization that has been built up in the last forty years. Although our sanatoriums and clinics have not been the only factors responsible for the decline of 80 per cent in the tuberculosis mortality in that period, they are the most effective weapons we possess for checking any upsurge of the insidious enemy. Prevention, far more than treatment, has been responsible for the gains that have been made, and so long as we prevent the spread of infection from open cases we shall be able to check the infiltration of our population that results in ultimate disaster.

At the beginning of the present war, the English promptly discharged to their homes a large number of patients in tuberculosis sanatoriums to make room for expected military casualties. When it was found that the beds were not needed, these tuberculosis cases were gradually returned to their hospitals, but the tuberculosis service was seriously disrupted and the damage that resulted from returning a large number of patients with contagious lesions to their homes and communities is hard to estimate. It is to be hoped that we profit by our neighbor's experience and retain, so far as possible, the exceptionally adequate sanatorium system we have built up.

Recruitment of physicians and nurses for military needs is bound to throw additional burdens on local boards of health, which have the primary legal responsibility for tuberculosis control. It is essential that reporting of cases be prompt and complete and where every doctor's load has been doubled he must depend more and more on the local public-health nurse for the follow-up and instruction of tuberculosis patients and their families that are so vital a part of prevention. When the patient has gone

\*A "Green Lights to Health" broadcast given through Station WAAB by Dr. Alton S. Pope on Saturday, February 7, and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

o the sanatorium, it is often the nurse's responsibility to see that the other members of the family come in for x-ray examination, and when necessary, receive adequate aid during the sickness of the wage earner.

Nutrition is perhaps the most vital factor in tuberculosis control in wartime. In the last war, the tuberculosis mortality was in general proportional to the inadequacy of the food supply, and in the neutral countries a rise became noticeable only when meat and dairy products had been depleted by combatant neighbors. Nutrition has always played an important part in the treatment of tuberculosis and there is every reason to believe it can play an equally significant role in prevention. A striking example of the correlation between nutrition and tuberculosis mortality is the situation in Germany twenty years ago. Three years after the armistice, the mortality had fallen nearly to prewar levels, but in the economic collapse of 1922-1923 the food shortage became almost as acute as it had been in 1918 and the tuberculosis mortality promptly rose about 50 per cent.

During the recent depression in the United States, tuberculosis experts freely predicted a general rise in the incidence of the disease, which to date has not materialized. The most reasonable answer seems to be that in spite of the great reduction of income for most of our population, the people on relief were on the whole more adequately fed than they had been during some periods of plenty. In other words malnutrition to be a factor in the activation of tuberculosis must apparently reach a certain critical level and if we can prevent its reaching that point by proper husbanding of our supplies and by judicious planning of our diets there is reason to hope that we can minimize one of the hazards that has seemed an inevitable part of war.

In no field of social welfare has this country been backward as in housing and it is doubtful whether any social factor more seriously complicates tuberculosis control under war conditions. The spread of tuberculosis depends on two things: the transmission of the causative organism, and the resistance of the human host. Obviously, the closer the contact between the open case and a susceptible host, the more rapidly will the disease spread and no factor is more favorable to such rapid transfer than overcrowding in poorly lighted and inadequately ventilated tenements. It is of course too late to correct such a situation in the face of more pressing demands, but we can at least make every effort to discover active cases of tuberculosis and remove them to a safer environment.

Difficult as it is to maintain the existing facilities for the prevention and treatment of tuberculosis under wartime conditions, those very conditions open certain new avenues of attack. First among them has been the opportunity to secure preinduction x-ray examinations of practically all men entering the armed forces of the country. Because the Army Medical Corps was not prepared to undertake these examinations in Massachusetts when the Selective Service Act went into effect in the fall of 1940, the State Department of Public Health took on the task through its field clinic unit by means of portable x-ray apparatus. Films were furnished by the Army and exposed and interpreted by the clinic staff. In the course of a year 10,000 members of the Massachusetts National Guard and 23,000 selectees were x-rayed and 134 cases of significant tuberculosis were found, an incidence of approximately 0.5 per cent. With the institution of its own apparatus this work has now been taken over by the Army Medical Corps and the preliminary screening of

all recruits promises to reduce substantially the future needs for treatment and compensation of soldiers disabled by tuberculosis—an expense that has reached a cumulative total of nearly \$1,000,000,000 since the last war.

Treatment for recruits found to have tuberculosis is fortunately immediately available in Massachusetts. Some, however, who are disqualified by a history of tuberculosis or inactive lesions offer a real problem in rehabilitation. The New England Rehabilitation Center at Rutland has limited facilities for the training and placement of suitable candidates, but a problem remains that is a real challenge to boards of health and especially to voluntary tuberculosis associations.

The staggering demands made on industry for munitions equipment and supplies of every description have made employers receptive to procedures that promise to improve the health and efficiency of their workers and thereby reduce the labor turnover. In the textile, boot and shoe, and some other industries it has been possible to make arrangements for mass x-raying of certain groups of employees for tuberculosis case finding. Consent of the workers has been obtained through their labor unions, and reports of the findings are given to the employees only. In the groups examined, the incidence of tuberculosis has not been high,—1.5 per cent, including healed cases,—but the active cases found are at a stage favorable for treatment and a certain number of foci of infection can be removed from the factories. Even more encouraging has been the arrangement by a few firms for the pre-employment x-ray examination of their own employees. It is quite possible that such control measures which have proved their value under the pressure of wartime production, will be accepted as an essential part of our program for the elimination of tuberculosis when a return to normal living has again made that aim a rational objective.

## DEATHS

DIEZ—M. LUISE DIEZ, M.D., of Boston, died April 12. She was in her sixty-fourth year.

Dr. Diez received her degree from the Woman's Medical College of Pennsylvania in 1903. Since 1929, she was director of the Division of Child Hygiene of the Massachusetts Department of Public Health. Dr. Diez was a member of the executive committee of the Massachusetts Child Council and of the Committee on Maternal Welfare of the Massachusetts Medical Society, a fellow of the American Public Health Association and a lecturer on child hygiene at the Harvard School of Public Health. She was a member of the Massachusetts Medical Society and the American Medical Association.

GALVIN—WILLIAM GALVIN, M.D., of North Adams, died April 8. He was in his eighty-fourth year.

A native of Troy, New York, Dr. Galvin received his degree from the University of Vermont College of Medicine in 1892. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by a niece.

It is essential that reporting of cases be prompt and complete and where every doctor's load has been doubled he must depend more and more on the local public-health nurse for the follow-up and instruction of tuberculosis patients and their families that are so vital a part of prevention. When the patient has gone

\*A "Green Lights to Health" broadcast given through Station WAAB by Dr. Alton S. Pope on Saturday, February 7, and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

failed to respond to specific antiserum, that sulfapyridine had a more marked effect on the pneumococcus but also resulted in more toxic reactions, which often caused earlier cessation of therapy than was considered optimal. That sodium sulfapyridine allowed preenteral administration of this drug during the critical vomiting period, that sulfathiazole caused only half as much nausea and vomiting but that larger doses were necessary on the whole to maintain similar blood levels, because of the more rapid metabolism of this drug, and that sulfadiazine results in nausea and vomiting in only 10 per cent of patients, and is generally a less toxic and more effective drug, but is still not ideal. Sulfadiazine is like sulfathiazole—in its direct contrast to sulfanilamide—in its negligible effect on erythrocytes. Agranulocytosis is not unknown in these two more recent compounds, especially after long periods of therapy, and toxic rashes also occur in 4 to 5 per cent of cases under the same circumstances.

The most serious complications are those involving the urinary tract. Fortunately, however, large amounts of fluids can be administered with sulfathiazole and sulfadiazine, without excretion of the drugs in proportionately large amounts—as with sulfanilamide. Also, these compounds have the advantage of being more soluble in the acetylated form. Sulfapyridine usually causes pain and hematuria as initial manifestations, and the crystals are deposited along the level of the tubules, thereby allowing early diagnosis and halting. Sulfathiazole therapy, on the other hand, may result in anuria without any previous manifestation because its crystals may be deposited in the tubules themselves. Sulfadiazine may also cause anuria, but only rarely if the urinary output is kept above 1500 cc per twenty-four hours.

In a recent series at the Boston City Hospital, the gross mortality with sulfadiazine was only 10.7 per cent. For patients under fifty years of age it was 2.9 per cent and in the nonbacteremic cases 7.6 per cent. This contrasts with 21.6 per cent for patients over fifty years, and 24.7 per cent for those with bacteremia. Nineteen per cent of the patients had bacteremia. The mortality in the armed forces during the present war, therefore, should not exceed 2 per cent, in contrast to that of 25 per cent in World War I, it was estimated.

As a result of experiments on the relative efficacy of the four common sulfonamide compounds on the pneumococcus, hemolytic streptococcus, *Staphylococcus aureus* and the Friedländer bacillus,—as well as on their toxicities—it was concluded that sulfadiazine is thus far the drug of choice in all pulmonary infections.

Specific antipneumococcus serum is still useful in cases in which the responsible bacterium becomes resistant to chemotherapy. The only other reason for substituting serum for drug therapy is the onset of serious toxic symptoms although serum may be a useful adjuvant when there is a second positive blood culture or a very severe bacteremia. Second blood cultures should always be taken when the fever lasts more than twenty-four to thirty-six hours on chemotherapy. Chemotherapy with the sulfonamides may be started with a low leukocyte count so long as it is not due to previous administration of the drug and there are a reasonable number of granulocytes. The onset of drug fever, rash and delirium on the seventh to the tenth day is obviously not caused by pneumonia and the pulse usually remains slow.

When a patient suffering from chronic asthma develops fever, it is often well to administer some sulfonamide for sputum examinations in such cases invariably reveal the presence of pathogenic bacteria. Such therapy should be in addition to the usual asthma treatment for without the supplemental action of the latter, these patients do poor-

ly. The same line of attack in those with fever and congestive heart failure often leads to the success of otherwise inefficient cardiac therapy. Chemotherapy with the sulfonamides in such cases, however, should not be continued if there is no improvement in twenty-four to forty-eight hours. If the temperature shows an immediate response, treatment should be carried on for about five days.

Dr Finland discussed influenza and its complications. During the epidemic a year ago, a virus identified as influenza A was isolated in many cases, and a measurable antibody titer found. There were an unusual number of staphylococcal pneumonias of marked severity. These patients were usually sick about two or three weeks, and although there was a tendency for the formation of lung abscesses and empyema, recovery was the rule. On the other hand, there were patients who had a sudden recurrence of signs and symptoms shortly after their apparent recovery from the grippe, with severe cyanosis, cough, inability to rise sputum and sudden death. The pathological findings in these patients were similar to those of influenza patients of World War I. It is impossible to determine how many of these changes are attributable to the virus infection and how many to the superimposed pneumonia, therefore the etiologic agent of the latter should be treated, since there is as yet no adequate therapy for the virus of influenza. The question is often raised whether all influenza patients should be treated with sulfonamides but Dr Finland is not in favor of such a procedure except in epidemics in which there are many pulmonary complications and persistent fevers, and bacteria are cultured.

In conclusion Dr Finland answered questions. Fastness to the sulfonamide drugs is probably not a common or significant occurrence. All susceptibility to these drugs is relative, and if fastness is developed in any case, there is no use in attempting to substitute one drug for another, for these cases develop fastness to all.

No truly characteristic temperature chart is caused by drug fever, but there is usually not a commensurate increase of pulse and the patient does not look so ill as the chart indicates. Such a fever seldom occurs in less than a week, except rarely with sulfathiazole or when the patient fails to report previous treatment by his own physician.

Vaccines do not seem to offer much hope. There is no sound basis for their use as a protection against pneumonia, for there are about sixty strains of the pneumococcus and forty of the streptococcus, besides an unknown number of staphylococcal strains. This mitigates against the inclusion of all strains and anything less could not be considered adequate protection against any given case of pneumonia. Furthermore, staphylococcal and streptococcal vaccines afford only a temporary immunity, and the pneumococcus cultured from the throat is usually not the responsible organism in lobar pneumonia and therefore cannot be used as a criterion of what to include in a vaccine. The use of vaccines against influenza, however, may be important in the future. At present vaccines containing influenza A and the virus of dog distemper protect the ferret but are only suggestively valuable in man. Their efficacy appears to vary from place to place but may be increased in the future.

Serum therapy of pneumonia has not been entirely supplanted but is used in specific cases, namely, in patients over fifty years of age in those who suffer from chronic alcoholism, particularly delirium tremens and in those who fail to respond to chemotherapy. Dr Finland issued a caution against a false sense of security on the basis of a falling temperature in patients treated with sulfapyridine for this drug has an antipyretic as well as bacteriostatic

effect. The response to sulfathiazole and sulfadiazine is slower, so far as the temperature chart is concerned, but the patient invariably feels and looks better even before there is any temperature response. In children, all drugs are apparently efficacious and are less toxic. In fact, the mortality from pneumococcal pneumonia in infants and children has decreased from 30 to 3 per cent since the advent of chemotherapy, and serum is seldom necessary.

## BOOK REVIEWS

*Trauma and Disease.* Edited by Leopold Brahdly, M.D., and Samuel Kahn, M.D. Second edition. 8°, cloth, 655 pp., with 13 illustrations and 13 tables. Philadelphia: Lea and Febiger, 1941. \$7.50.

This book is a symposium on the relation of trauma to diseases of the various organs. The many authors are well qualified to write on their subjects. Such names as Paul White, Hugh Cabot, George Blumer and Elliott Joslin give a note of authority that a single author could not begin to achieve.

A great many unjust settlements for injuries are made largely because some authority such as this book has not been consulted by those who make the final decisions. Past decisions are unreliable in establishing liability or fair compensation. The new knowledge of disease, based on the study of pathology and physiology, calls for a new legal interpretation of disease as related to trauma. In this development, the present work will be a valuable aid.

Each organ or system of the body is considered separately, and the material is arranged so that reference is readily made to any desired subject. The book should be of great value to those members of the medical and legal professions who deal with compensation cases.

*Cardiac Classics: A collection of classic works on the heart and circulation, with comprehensive biographic accounts of the authors.* Compiled by Frederick A. Willius, M.D., and Thomas E. Keys, M.A. 4°, cloth, 858 pp., with 102 illustrations. St. Louis: The C. V. Mosby Company, 1941. \$10.00.

The authors have performed a useful service for the medical profession, especially for those interested in the development of the knowledge of cardiovascular disease, by assembling in one volume some of the more important original contributions. This book begins with a brief account of the influence of certain cardiac classics on the development of modern cardiology. The introduction is followed immediately by a complete transcription of William Harvey's classic treatise on the circulation of the blood, as translated by Robert Willis, of Barnes, Surrey, England, in 1847. The extensive quotation from Harvey is followed by contributions in whole or in part from fifty other authorities, ending with Sir James Mackenzie, Sir William Osler, James B. Herrick and Oliver Wendell Holmes ("The Stethoscope Song—A Professional Ballad").

No two persons would agree in every detail concerning the value of many of these contributions. The reviewer would like to have seen something quoted from several of the more important earlier writers not included here, such as Lower, Bonetus, Vieussens and Lancisi, but he has been compensated by an opportunity to become acquainted with several authors whose works he had not previously read.

One of the helpful and interesting parts of the book is the collection of brief biographies preceding each quotation. Among the other authors quoted whose names and works are best known are Malpighi, Hales, Senac, Morgagni, Auenbrugger, Heberden, Withering, Corvisart,

Laennec, Hope, Stokes, Flint, Roger, Steell, Broadbent, Einthoven and Keith.

At the end of the book are short tables giving the correlation of these classics with other contemporary historical events and a list of biographical references. A good many interesting illustrations are included, such as the pictures of some of the authors themselves, occasional title pages, pulse tracings, Laennec's stethoscope, and drawings of normal and pathologic hearts.

*Communicable Disease Control: A volume for the health officer and public health nurse.* By Gaylord W. Anderson, M.D., and Margaret G. Arnstein, R.N., M.A., M.P.H. 8°, cloth, 434 pp., with 13 tables. New York: The Macmillan Company, 1941. \$4.25.

This volume, which furnishes concise information in a clear form on the subject of communicable-disease control for the community, is a very valuable addition to the literature.

The chapter on the infectious process, in which an analogy is drawn between the effect of forces acting on a block in the physics laboratory and the forces of infection and resistance, is clearly expressed without recourse to unfamiliar terms, and gives one of the clearest presentations available in the literature.

General control measures are discussed, embodying the principles without undue verbiage. Legal basis for control is cited, and the various administrative agencies for control are briefly reviewed. There is an excellent chapter on the role of the public-health nurse, and one on the home care of patients with communicable diseases.

The book is consistent in discussing individual diseases. The pattern is always obvious, and one can immediately find the desired information under its appropriate heading for each disease discussed. The order is: occurrence of disease, the etiologic agent, the reservoir of infection, escape from the reservoir, transmission, entry and incubation period, susceptibility, control methods and minimizing ill effects.

The volume, which should be in the hands of every public-health official and nurse, will be a useful addition to the library of every general practitioner.

*Rheumatic Fever in New Haven.* Edited by John R. Paul, M.D. 8°, paper, 176 pp., with 22 tables and 45 charts. Lancaster, Penn.: The Science Press Printing Company, 1941. \$1.00.

This is an epidemiologic study of rheumatic fever. Although the etiology of this disease is obscure and there are no definite tests available for diagnosis, much can be learned of the public-health aspects of rheumatic fever by the statistical method. The incidence of the disease was calculated from hospital admissions in the three large hospitals in New Haven. The active cases made up 1.2 per cent of the admissions to the medical services. The incidence of rheumatic heart disease was found to be somewhat lower among a group of relatively well-to-do students of Yale University, but the factor of poverty does not seem to have so important a predisposing role in determining the incidence of rheumatic heart disease as it does in tuberculosis. The disease is distributed fairly evenly among people of different nationalities. The clinical entity of rheumatic fever is rarely precipitated in a normal person as a result of his first contact with the infectious agent. The author believes that the infant must grow up to be a rheumatic. Poverty and crowding, according to this study, do not appreciably enhance the prevalence of rheumatic fever.

## VOLKMANN'S ISCHEMIC CONTRACTURE\*

### An Analysis of Its Proximate Mechanism

PHILIP S. FOISIE, M.D.†

BOSTON

SINCE 1871, when von Volkmann first described the contracture deformity that bears his name, has commonly been accepted as a complication of the improperly treated supracondylar fracture of the humerus. This paper presents evidence that Volkmann's ischemic contracture has no essential connection with such a fracture or any other specific injury but is the result of ischemic necrosis produced by segmentary arterial spasm of the main artery to an extremity, with reflex spasm of the collateral circulation. Thus, a subtotal ischemia is produced, and the muscle bellies, which have the greatest demand for arterial blood and are therefore the most vulnerable tissue to loss, are the first affected. Gangrene of the fingertips or partial or even complete gangrene of the extremity would result if this spasm continued to a sufficiently severe degree, but where Volkmann's contracture is to be the only result, some improvement in the arterial supply intervenes. This vasomotor activity is under control of the sympathetic nervous system, and will be discussed more fully after the actual clinical picture has been considered.

The problem can be further defined by the statement that only the acute stage of Volkmann's contracture is concerned in this study. Whatever may be the responsible factors, the condition initially is one of impaired circulation. In the old cases of established deformity, normal blood supply has returned, and the problem is entirely one of correcting existing deformity by physiotherapy, tendon lengthening, bone shortening and so forth. These procedures have been discussed elsewhere, and are not considered in this paper, which is limited to a discussion of

Volkmann's contracture in its acute stage, the actual mechanism producing the ischemia and the logical methods of correcting the causative lesion; the goal of treatment is to restore adequate circulation before irreparable damage is done, and thus to avert contracture deformities.

### RECENT CLINICAL EXPERIENCE

In the literature of the last five years, most particularly in the last two years, from France, England, Switzerland and occasionally from South America, numerous articles, mostly from unrelated sources, have described the operative findings in explored cases of early Volkmann's syndrome. Thirty of these case histories were reviewed, and findings of the various operators were strikingly similar. The antecedent injury was usually a fracture or bullet wound of the upper arm. In about twenty-four hours, definite signs of ischemia appeared: the hand became cold and swollen, with usually a pale cyanosis, and the fingers became functionless. Pain was a prominent symptom, especially on any attempt at motion of the fingers, either active or passive. The radial pulse was absent. If the condition was further observed, the next day the fingers usually assumed a position of flexion, and any attempt to straighten them caused considerable pain. When apparatus was used to maintain extension of the fingers, the patient could not tolerate it for long, even with repeated doses of morphine, and it invariably had to be removed. In these cases, the surgeon, after intervals varying from twenty-four hours to three weeks, finally decided to explore the injured site. It is interesting that in most cases the surgeon had not explored such an injury before and was not prepared for what he found. He went in expecting to find some mechanical obstruction to the arterial flow, angulation of the artery over the

proximal fragment or pressure of fragments on the artery, hematoma or some other mechanical disturbance that he hoped to be able to correct; accordingly, these men could certainly not be accused of the possible inclination of an enthusiast to read into his findings something that he was looking for. This, I think, gives added weight to the observation that in every case a profound segmentary arterial spasm was encountered. The operative note might have been as follows:

A longitudinal incision was made medial to the biceps tendon, and in the lower half of the incision, no bleeding occurred. The muscle, which herniated through the superficial fascia when it was incised, appeared gray and lifeless. There was some extravasated old blood, but no hematoma under pressure. The median nerve was not remarkable. The brachial artery, however, presented a most astounding picture. At a point about 2 cm. above its bifurcation, it was pulsating normally, was even perhaps a little dilated, but there it suddenly became narrowed to a stringlike size extending down into the radial and ulnar branches.

The foregoing description is not taken from any one case but is a synthesis of so many reports that it is almost universally applicable. The methods by which these surgeons attempted to treat the patients are discussed below. The important point is that in patients presenting definite signs of an early Volkmann's syndrome with an absent radial pulse, a cold pallid ischemia and a beginning flexion deformity of the fingers, exploration generally revealed a segmentary spasm of the main artery. Although arterial spasm of varying degrees has been recognized in many peripheral vascular disorders, it has not until very recently been suspected of being responsible for such severe ischemia, and this series of cases establishes arterial spasm as a phenomenon to be reckoned with.

#### PATHOLOGY

As a background for this discussion of how the established Volkmann's contracture is produced by this mechanism, a review of its pathology is necessary. It is essentially an atrophy of the flexor muscle bellies, whose destruction results in an apparent shortening of the flexor tendons, pulling the fingers and sometimes the wrist into acute flexion (Fig. 1). In the less severe cases, by flexion of the wrist, the fingers can be extended and vice versa, but extension of both fingers and wrist is not possible at the same time. In the severer cases, neither can be done.

One of Griffiths's<sup>1</sup> contributions to this subject is his very precise description of the morbid anatomy. The gross picture, which is one of central degeneration of the muscle bundle, is duplicated histologically by only one other condition, infarction. In both, there is a picture of mass

necrosis; the most extensive degeneration occurs in the center of the muscle sequestrum, and cellular activity and fibrosis take place only at the periphery, which is surrounded by a sheath of

FIGURE 1. *Clinical Deformity in a Case That Was Not Severe to Begin with and That Was Further Improved by Operative Lengthening of the Flexor Tendons.*

*Note the atrophy of the forearm. With the wrist flexed, the fingers could be fully extended, and with the fingers flexed, the wrist could be fully extended, but both could not be done at once.*

dense fibrous tissue. In the center of the mass, the muscle fibers lose their nuclei and cross striations, and fuse into a homogeneous mass, little more than a defining membrane separating them (Fig. 2). As the periphery is approached, some

signs of function are preserved, and there is an area of intense cellular activity, both fibroblastic and phagocytic (Fig. 3). This picture is in contrast to muscle degeneration from all other causes, such as denervation and sepsis, when the appearance is one of diffuse interfibrillar fibrosis (Fig. 4). This histology should be kept in mind when one considers the mechanism of the

FIGURE 2. Low Power View of a Cross Section of the Flexor Muscles of the Forearm in a Case of Volkmann's Contracture.

*Note the mass necrosis of the muscle bundles, with the greatest destruction in the center and with the cellular activity limited to the periphery (Griffiths<sup>1</sup> reproduced with permission of the publisher)*

ischemia. It is also of value in animal experimental work in determining whether or not a true Volkmann's contracture has been produced

#### ETIOLOGY

The fact that supracondylar fracture of the humerus is the commonest initial injury that Volkmann's contracture may complicate has perhaps led many to associate the contracture exclusively with such fractures. The location of this fracture and the related displacement that commonly occurs unquestionably bring into play many factors tending to impair circulation of the forearm. Among these are the possible angulation of the brachial artery over the edge of the proximal fragment, the damage to soft tissue from spicules of bone and, most commonly mentioned, the possibility of hemorrhage into the antecubital fossa, with the formation of a hematoma confined by the unyielding deep fascia and thereby tamponading the venous return. It has been pointed out that such a pressure hematoma is especially effective at this point because the venous

return from the forearm converges into a plexus that is particularly vulnerable to local pressure. If to this is added a difficult and unskillful reduction, and the application of some constricting apparatus in a position of acute flexion, the *coup de grâce* may be administered to the circulation of the forearm.

That this is a reasonable and adequate picture of circulatory embarrassment cannot be denied and, in fact, very logically explains its almost unchallenged acceptance for so long. And I have no desire to suggest that these factors are not important. It is obvious that in any situation in which ischemia is present, any factor that impairs circulation in any way must never be tolerated. No doubt, it is possible to shut off the circulation to any extremity by overly tight splints, and perhaps on occasions this has been done. It is self-evident that prompt, gentle and skillful reduction, and properly applied fixation are fundamental

FIGURE 3. High Power View of the Specimen in Figure 2.

*Note that the muscle fibers near the periphery retain their cross striations and are more nearly normal (Griffiths<sup>1</sup> reproduced with permission of the publisher)*

essentials. Given these, this syndrome has developed right under the eyes of the most capable surgeons; even when they had the opportunity of treating the patient from the beginning.

The chief evidence that the factors of venous occlusion and constriction of overly tight apparatus do not constitute the essential mechanism of Volkmann's ischemia is that actually the syndrome commonly develops in the complete absence of such causes. In cases of supracondylar fracture in which these factors might reasonably be expected and in which the fracture site has been

exposed by open operation, the subfascial hematoma as such has rarely been found. There is a certain amount of old blood clot and loose hemorrhage in the tissues as at any fracture site, but no specifically confined mass. The most approved treatment has consisted in multiple drainage incisions through the fascia; but this procedure, in addition to the removal of all apparatus, has in many cases not improved the circulation, and when improvement occurs, the artery itself has usually been exposed and freed. I consequently believe

FIGURE 4. Cross Section Showing the Histologic Picture of the Muscle Atrophy from All Other Causes.

*Note the diffuse interfibrillar fibrosis, as contrasted with the picture in Figures 2 and 3. This difference seems to be the best argument against the theory of venous occlusion, since one would expect the above picture if Volkmann's contracture was the result of venous occlusion, with edema and retention of metabolic waste products (Griffiths<sup>1</sup>: reproduced with permission of the publisher).*

that the procedure has fortuitously achieved the result of releasing reflex arterial spasm.

Further evidence against these factors is that this particular injury, which most favors their presence, is by no means the only one that Volkmann's ischemia may follow. It occurs in practically all fractures of the upper extremity, even those as far removed as the clavicle, in several other injuries to soft parts in which no fracture has occurred, and in similar injuries of the lower extremities. Hill and Brooks,<sup>2</sup> in 1936, reviewed the literature and found 123 cases without the previous application of any constricting bandage or splint, and 28 cases in which there was neither any fracture nor constricting bandage or splint. Furthermore, many cases of soft-tissue injury with only moderately severe trauma are described, and

Griffiths<sup>1</sup> reports 3 cases following arterial embolism from heart disease in which there was no trauma of any kind.

These facts may afford some comfort to the surgeon who has seen this complication develop in a patient under his care. They suggest that the proximate mechanism is initiated by the injury itself rather than by the treatment, and that it is an ischemia intrinsically arterial in which other factors are only secondary.

#### ARTERIAL SPASM

Leriche<sup>3</sup> has written a great deal on circulatory equilibrium, which is ensured for each structure by the action of the vasomotor nerves. These nerves adapt the local circulation to the regional requirements by vasoconstriction or vasodilatation as a result of constantly changing stimuli. Leriche differs from many physiologists in his opinion that the sympathetic system contains sensory as well as motor fibers and that the sympathetic ganglion plays the role of reflex center. It is easy to believe, therefore, that the sympathetic system may have a definite role to play in injury by which a local temporary arterial spasm may be set up to prevent overextravasation of blood or fatal hemorrhage from a severed artery. If these stimuli are not removed, or if the patient has an especially labile vasomotor reflex, the spasm may persist beyond its physiologic requirements and may even spread to include the collateral circulation.

Varying degrees of arterial spasm are encountered in many peripheral vascular disturbances. Homans's<sup>4</sup> book on circulatory diseases of the extremities contains a whole chapter on this subject. There is, no doubt, a difference in the mechanism of production between a generalized vasoconstriction and local segmentary spasm; the former is probably due to central innervation and the latter is possibly the result of a local reflex. This point was brought out by Homans<sup>5</sup> in discussing a case of his in which an adequate and satisfactory ganglion injection failed to relieve a local arterial spasm; about twenty-four hours later, the foot became suddenly flushed with an extensive vasodilatation. He logically concluded that local spasm may be effected by a distal reflex arc that does not include the ganglion. Injury need not directly affect the vessel to produce arterial spasm. The following case illustrates this fact.

CASE 1. A young, muscular, colored man was admitted to the Boston City Hospital immediately after an altercation with some "friends." The admission diagnosis was bullet wounds of the chest and of the right upper arm and surgical shock. I happened to be in the hospital at the time, and I went to see the man immediately, being concerned particularly about the shock aspect of the diagnosis. To my surprise, I found him reclining on one elbow,

chewing gum, and grinning with considerable self satisfaction. Obviously, he was not in any surgical shock. I picked up his wrist to feel his pulse, but there was none. The house officer who had admitted him had apparently made the same finding, which accounted for the shock diagnosis, but had neglected to feel the opposite arm, where the patient had a perfectly good full pulse and a systolic blood pressure of 140. Examination of the chest revealed that the bullet wound was superficial, and there were no signs of damage to the lungs, the problem boiled down immediately to the wound of the right upper arm, where there were bullet wounds of entrance and exit through the fleshy portion of the biceps. There was some swelling of this area, but the arm was not grossly distended or tense, and x-ray examination revealed no fracture of the humerus. We believed that some damage had probably been done to the brachial artery, and immediately explored it. Going through the muscle, we found a certain amount of extravasation of blood but no gross hematoma, at least, no hematoma under pressure sufficient to occlude the artery. On exposing the artery itself, we were surprised to find that at a point about 2 cm above its bifurcation, it was constricted to a stringlike structure. We picked it up and freed it, and followed it along down with the idea of seeing how far this constriction continued, when all of a sudden it began to pulsate and filled with blood. A bystander who was asked to palpate the radial pulse reported that there was good pulse at the wrist. We simply closed the wound, and the patient made an uneventful recovery and never subsequently had any circulatory disturbance in this extremity.

This patient had no direct trauma to the artery, nor was there sufficient extrinsic pressure to occlude it mechanically. He did not, at least at the time of operation, have the essential elements of a Volkmann's contracture because there was still good collateral circulation. Left alone, he might either have spontaneously relieved the local spasm or later developed reflex collateral spasm. I should probably treat a similar case by ganglion injection, followed by surgical intervention only if collateral circulation became impaired.

Sometimes, segmentary spasm is produced by minor injury to the arterial wall that is not sufficient to occlude the artery by the damage per se but causes the artery to occlude itself. Griffiths<sup>1</sup> describes a patient who was pulseless after satisfactory reduction of a supracondylar fracture. He explored and found no subfascial hematoma, but did find a hematoma no larger than a millet seed in the anterior wall of the brachial artery near the site of fracture. Despite the small size of this hematoma, the brachial artery and its radial and ulnar branches were collapsed and pulseless. Mobilizing and stripping the brachial artery produced no change, but after resection of the damaged portion, the circulation made a complete recovery and no deformity resulted. Griffiths also mentions a case in which the brachial artery showed a very localized intramural rupture, which presented complete spasm from the subclavian artery downward. Several cases are presented in the

literature in which resected sections of artery showed, on pathological study, small defects not grossly visible.

Montgomery and Ireland<sup>6</sup> encountered localized arterial spasm in 2 cases, and were stimulated to search the literature for others; in 1935, they reported 44 cases of what they termed "traumatic segmentary arterial spasm," resulting from all kinds of trauma, but of which 26 were the result of gunshot or high explosive injuries. In 1940, Gage and Ochsner<sup>7</sup> published an excellent report in which arterial spasm is discussed quite fully. They were dealing with the subject of operative procedures on peripheral arteries. They mentioned particularly a so-called "butcher's injury," which results from slipping of the knife during the skinning of beef; a stab wound of the upper medial aspect of the thigh commonly results with injury of the femoral vessels or perivascular tissue in the upper end of Hunter's canal. They noted that in many cases, even when the vessels were not severed, reflex vasospasm was of such severity that the clinical manifestations were identical with those of complete arterial occlusion.

Arterial spasm is also seen following lodgment of emboli, and in fact may result from any disturbance of the peripheral circulation. Homans<sup>4</sup> states that it is known to occur with venous thrombosis, especially the inflammatory sort. One writer<sup>8</sup> graphically referred to this spasm as "arterial colic."

#### COLLATERAL CIRCULATION

Griffiths's<sup>1</sup> Hunterian Lecture on Volkmann's contracture is the most modern complete discussion of this subject in the literature, and deserves the careful study of everyone interested in the subject. Of the many contributions he makes, I think that the most important is his demonstration by animal experiments that the key factor in the development of Volkmann's contracture is the loss of the collateral circulation. The danger to the peripheral tissues of a main artery in spasm is not so much the loss of the artery itself as a blood-carrying channel as it is the possibility that this spasm may spread to include the collateral circulation as well. Normally, with the main vessels intact, the collateral circulation functions only to a small percentage of its full potential, but its presence affords an alternate route that can, if necessary, be developed to furnish adequate circulation in lieu of the main artery. There are certain anatomic weak points in this system; namely, the common femoral artery, the carotid artery at its bifurcation and the popliteal arteries, about which collateral circulation is not abundant; the regions about the shoulder, elbow, hip, hand

and foot, however, are abundantly supplied. When occlusion of the main artery is a gradual process, simultaneous hypertrophy of the collaterals occurs, and no embarrassment of circulation results. The strain is much greater on the collaterals when the occlusion of the main artery is sudden, and circulation is further imperiled by the fact that the collaterals are subject to the same sympathetic control as the main vessel. Thus, a vicious circle is possible in that if spasm of the main artery becomes fixed beyond its normal physiologic intentions, the same condition may spread to the collaterals at a time when their increased function is needed. It has been shown by oscillometer readings that, with a main artery occluded, reflex vasospasm not only may obstruct the collateral circulation of that extremity but also may affect the opposite side, and even extend to the lower extremity. Thus, without extrinsic pressure, a total or subtotal ischemia may be produced that will result only in muscle atrophy if the ischemia is relatively temporary, and in varying degrees of gangrene if the ischemia is prolonged.

Leriche et al.,<sup>9</sup> working with dogs, were able to resect all the large arteries of the hind legs, beginning distally and operating in eight or nine successive stages spaced at intervals of from ten to thirty days. In this manner, they removed the posterior tibial, the anterior tibial, the femoral, the inferior gluteal, the lateral sacral, the hypogastric, the external iliac and, in the final stage, the common iliac arteries and the bifurcation of the aorta. Carrying out this procedure, they encountered only occasional temporary edema, which rapidly disappeared. These dogs, literally "without arteries," were able to run, stand on hind legs, and jump as normal animals. When the authors attempted initially to resect the common iliac arteries and the bifurcation of the aorta, all the animals promptly died, but if this procedure was preceded by resection of the lumbar sympathetic ganglions, the animals were only slightly disturbed by this extensive arterectomy.

Gage and Ochsner<sup>7</sup> discovered the value of developing the collateral circulation by ganglion block prior to operative procedures on peripheral arteries.

It is evident that good collateral circulation is capable of amply supplying all the needs of the peripheral tissues, and that the chief danger in cases of main-artery occlusion lies in the degree of constriction or dilatation of the collaterals that are under sympathetic vasomotor control. Griffiths, in his animal experiments, showed this loss of the collateral circulation to be the determining factor in the development of Volkmann's contracture.

## TREATMENT

It should be emphasized that time is a major factor in treatment. This syndrome is a progressive one in which more and more damage is done. The value of early action is apparent. In the first place, all measures favoring circulation generally are of fundamental value. These include elevation of the part, removal of any apparatus or circular bandaging, and the application of mild external warmth.

The next logical step is the interruption of the sympathetic reflex arc. Theoretically, one might expect to accomplish this by ganglion injection, periarterial sympathectomy or arterectomy. Ganglion block, which is the simplest of these methods, should be tried first. Its results will be apparent at once, and if the procedure is successful, an open operation is avoided. The following case illustrates its use.

CASE 2. A 53-year-old woman was admitted to the Boston City Hospital on September 1, 1941, with a trimalleolar fracture of the left ankle. A Kirschner wire was inserted for traction, and open reduction was later performed under an Esmarch bandage. The operation lasted an hour and a half. The next day, the foot was cold, cyanotic, swollen and painful. The dorsalis pedis and popliteal arteries were not palpable. A lumbar block was done that afternoon. Forty cubic centimeters of novocain was injected, about 15 cc. through each of three needles, and 15 minutes after this procedure, the circulation improved. The following day, both the dorsalis pedis and the popliteal arteries were palpable; 1 week later, swelling of the toes was entirely gone, the foot was warm and pink, the wounds were clean, and the chart was flat. The patient had no subsequent circulatory difficulty.

Lumbar block is now a common procedure when peripheral dilatation is desired, and needs no further comment. Injection of the stellate ganglion is perhaps not so familiar, but reports of surgeons in the French army indicate that it is now being frequently employed in the relief of peripheral spasm of the upper extremity. Luzuy,<sup>10</sup> who apparently was called on to attend a large number of fresh injuries, states that he has had occasion to employ this procedure as often as several times a day. The appearance of the Bernard-Horner syndrome within a few minutes is evidence of successful cervical sympathetic paralysis.

The possibility that local arterial spasm may be the result of a local reflex that does not include the paravertebral ganglions means that this procedure cannot be expected to be universally successful; if circulatory improvement is not promptly apparent, or if initial improvement is not maintained, the artery should be exposed. The adherents to the theory of venous occlusion have logically treated this syndrome by multiple inci-

sions through the deep fascia to afford drainage and relieve pressure. This procedure has been successful in cases in which venous congestion was the main secondary factor, producing the arterial spasm that was the proximate cause of the ischemia. It has failed in many cases when other factors were in effect. I believe that it is therefore more logical to approach the problem directly—to expose the artery by careful dissection. This at once accomplishes effective relief of

of circulation resulted in every case, and complete return of normal circulation and function in most cases. In only 1 case<sup>12</sup> did a poor result occur, this patient was said to have had paralysis of the radial, median and ulnar nerves as well, so that the case could hardly be included in a series of pure Volkmann's contractures.

Arterectomy may appear to be a radical procedure,\* and a natural reaction is to try to save the artery and hope to reestablish function of

FIGURE 5 Arteriographic Study in a Case of Volkmann's Contracture  
Note the segmentary spasm of the lower end of the brachial and the upper ends of the radial and ulnar arteries (Leisner<sup>12</sup>)

any abnormal venous pressure, determines whether any local trauma to the artery has been sustained, and affords opportunity for complete sympathetic interruption by periarterial sympathectomy or arterectomy.

Concerning the respective values of these two procedures, there is some difference of opinion among those surgeons who have had some experience in their use. In the series of 30 cases mentioned above, arterectomy was performed in 10, periarterial sympathectomy in 5, and various procedures in the rest—including freeing up of the artery, novocain injection, ligation and simple loose closure. The arterectomy group invariably gave the best results. Definite improvement

this blood carrying channel. Objections to this are that the alternative periarterial sympathectomy on an extremely contracted artery may be technically difficult, and that interruption of the sympathetic control is the main goal in view. Arterectomy has the advantage of complete interruption of the reflex, in addition to the removal of a segment of artery that possibly contains a small break or tear, not grossly visible, but sufficient to maintain continued abnormal sensory stimuli. Arteriographic studies in late cases of Volkmann's contracture have shown a persistently interrupted segment of the main artery (Fig 5), although satisfactory

\*A 3 cm. to 5-cm. segment of the contracted artery is removed with simple ligation of both free ends.

and foot, however, are abundantly supplied. When occlusion of the main artery is a gradual process, simultaneous hypertrophy of the collaterals occurs, and no embarrassment of circulation results. The strain is much greater on the collaterals when the occlusion of the main artery is sudden, and circulation is further imperiled by the fact that the collaterals are subject to the same sympathetic control as the main vessel. Thus, a vicious circle is possible in that if spasm of the main artery becomes fixed beyond its normal physiologic intentions, the same condition may spread to the collaterals at a time when their increased function is needed. It has been shown by oscillometer readings that, with a main artery occluded, reflex vasospasm not only may obstruct the collateral circulation of that extremity but also may affect the opposite side, and even extend to the lower extremity. Thus, without extrinsic pressure, a total or subtotal ischemia may be produced that will result only in muscle atrophy if the ischemia is relatively temporary, and in varying degrees of gangrene if the ischemia is prolonged.

Leriche et al.,<sup>9</sup> working with dogs, were able to resect all the large arteries of the hind legs, beginning distally and operating in eight or nine successive stages spaced at intervals of from ten to thirty days. In this manner, they removed the posterior tibial, the anterior tibial, the femoral, the inferior gluteal, the lateral sacral, the hypogastric, the external iliac and, in the final stage, the common iliac arteries and the bifurcation of the aorta. Carrying out this procedure, they encountered only occasional temporary edema, which rapidly disappeared. These dogs, literally "without arteries," were able to run, stand on hind legs, and jump as normal animals. When the authors attempted initially to resect the common iliac arteries and the bifurcation of the aorta, all the animals promptly died, but if this procedure was preceded by resection of the lumbar sympathetic ganglions, the animals were only slightly disturbed by this extensive arterectomy.

Gage and Ochsner<sup>7</sup> discovered the value of developing the collateral circulation by ganglion block prior to operative procedures on peripheral arteries.

It is evident that good collateral circulation is capable of amply supplying all the needs of the peripheral tissues, and that the chief danger in cases of main-artery occlusion lies in the degree of constriction or dilatation of the collaterals that are under sympathetic vasomotor control. Griffiths, in his animal experiments, showed this loss of the collateral circulation to be the determining factor in the development of Volkmann's contracture.

## TREATMENT

It should be emphasized that time is a major factor in treatment. This syndrome is a progressive one in which more and more damage is done. The value of early action is apparent. In the first place, all measures favoring circulation generally are of fundamental value. These include elevation of the part, removal of any apparatus or circular bandaging, and the application of mild external warmth.

The next logical step is the interruption of the sympathetic reflex arc. Theoretically, one might expect to accomplish this by ganglion injection, periarterial sympathectomy or arterectomy. Ganglion block, which is the simplest of these methods, should be tried first. Its results will be apparent at once, and if the procedure is successful, an open operation is avoided. The following case illustrates its use.

CASE 2. A 53-year-old woman was admitted to the Boston City Hospital on September 1, 1941, with a trimalleolar fracture of the left ankle. A Kirschner wire was inserted for traction, and open reduction was later performed under an Esmarch bandage. The operation lasted an hour and a half. The next day, the foot was cold, cyanotic, swollen and painful. The dorsalis pedis and popliteal arteries were not palpable. A lumbar block was done that afternoon. Forty cubic centimeters of novocain was injected, about 15 cc. through each of three needles, and 15 minutes after this procedure, the circulation improved. The following day, both the dorsalis pedis and the popliteal arteries were palpable; 1 week later, swelling of the toes was entirely gone, the foot was warm and pink, the wounds were clean, and the chart was flat. The patient had no subsequent circulatory difficulty.

Lumbar block is now a common procedure when peripheral dilatation is desired, and needs no further comment. Injection of the stellate ganglion is perhaps not so familiar, but reports of surgeons in the French army indicate that it is now being frequently employed in the relief of peripheral spasm of the upper extremity. Luzuy,<sup>10</sup> who apparently was called on to attend a large number of fresh injuries, states that he has had occasion to employ this procedure as often as several times a day. The appearance of the Bernard-Horner syndrome within a few minutes is evidence of successful cervical sympathetic paralysis.

The possibility that local arterial spasm may be the result of a local reflex that does not include the paravertebral ganglions means that this procedure cannot be expected to be universally successful; if circulatory improvement is not promptly apparent, or if initial improvement is not maintained, the artery should be exposed. The adherents to the theory of venous occlusion have logically treated this syndrome by multiple inci-

sions through the deep fascia to afford drainage and relieve pressure. This procedure has been successful in cases in which venous congestion was the main secondary factor, producing the arterial spasm that was the proximate cause of the ischemia. It has failed in many cases when other factors were in effect. I believe that it is therefore more logical to approach the problem directly—to expose the artery by careful dissection. This at once accomplishes effective relief of

of circulation resulted in every case, and complete return of normal circulation and function in most cases. In only 1 case<sup>11</sup> did a poor result occur; this patient was said to have had paralysis of the radial, median and ulnar nerves as well, so that the case could hardly be included in a series of pure Volkmann's contractures.

Arterectomy may appear to be a radical procedure,\* and a natural reaction is to try to save the artery and hope to re-establish function of

FIGURE 5 Arteriographic Study in a Case of Volkmann's Contracture

Note the segmentary spasm of the lower end of the brachial and the upper ends of the radial and ulnar arteries (Leteru<sup>12</sup>)

any abnormal venous pressure, determines whether any local trauma to the artery has been sustained, and affords opportunity for complete sympathetic interruption by periarterial sympathectomy or arterectomy.

Concerning the respective values of these two procedures, there is some difference of opinion among those surgeons who have had some experience in their use. In the series of 30 cases mentioned above, arterectomy was performed in 10, periarterial sympathectomy in 5, and various procedures in the rest—including freeing up of the artery, novocain injection, ligation and simple loose closure. The arterectomy group invariably gave the best results. Definite improvement

this blood carrying channel. Objections to this are that the alternative periarterial sympathectomy on an extremely contracted artery may be technically difficult, and that interruption of the sympathetic control is the main goal in view. Arterectomy has the advantage of complete interruption of the reflex, in addition to the removal of a segment of artery that possibly contains a small break or tear, not grossly visible, but sufficient to maintain continued abnormal sensory stimuli. Arteriographic studies in late cases of Volkmann's contracture have shown a persistently interrupted segment of the main artery (Fig 5), although satisfactory

\*A 3 cm. to 5 cm. segment of the contracted artery is removed with simple ligation of both free ends.

collateral circulation had eventually been established. If the artery is going to maintain a contracted state, it is of no value as a blood carrying channel, and the removal of this contracted segment is not a circulatory loss.

Leriche et al.<sup>9</sup> urge arterectomy on the ground that a constricted artery that has no blood flowing through it but still has its sympathetic fibers running through its adventitia is in effect not an artery at all, but is an abnormal sympathetic nerve. To my mind, the most surprising feature in the results obtained in this group of cases is the improvement obtained in patients operated on comparatively late. Du Pan<sup>13</sup> reported a case in which arterectomy was performed over three weeks after the onset of symptoms, with complete recovery except for slight hypothermia and interosseus atrophy. This fact throws some doubt on Griffiths's conclusion that irreparable damage is done within the first twenty-four hours; he was probably influenced in this belief by the fact that flexion deformity of the fingers is one of the earliest signs to appear, but at this stage it could hardly be the result of cicatricial contraction. In discussing Massart's paper, Mutuel<sup>14</sup> brings up this point. He cites the observation that with a patient asleep or under an anesthetic, pressure of a blood-pressure cuff causes the fingers to flex. Browne<sup>15</sup> has spoken of this flexion as the position of "physiologic rest," and I believe that its assumption in the early stages simply means that the patient naturally assumes the position that is most comfortable and causes the least traction on the disturbed area. The subsequent permanent flexion deformity is the result in part of the fact that fibrosis occurs with the fingers in flexion to begin with; this deformity is further developed by subsequent cicatrization.

#### DISCUSSION

The mechanism of production and of the possible results of arterial spasm is a field new enough to be filled with opportunities for further study and many interesting possibilities, which are by no means limited to various circulatory disturbances of the extremities; to keep this discussion within reasonable bounds, however, one must for the moment curb any impulse to speculate, and consider only the subject at hand. It has probably always been taken for granted that arterial circulation is adequate unless the main artery is plugged, divided or shut off by external pressure, and therefore the realization that complete ischemia can be developed by the action of the artery walls is rather shocking. Still more interesting is the fact that the major arteries are by no means essential, and that the collateral circulation holds the balance between life and death of the peripheral

tissues. Volkmann's contracture is a result of a relatively temporary subtotal ischemia, which may be initiated by any injury or circulatory disturbance that sets this mechanism into action.

An interesting sidelight is that, because in most cases this complication is probably the result of the initial injury, many surgeons have been unjustly accused of unskillful treatment. Du Pan,<sup>13</sup> after reporting his case, confesses his guilt in this respect. He relates that he had always prided himself on the fact that this complication had never occurred in his clinic, a record that he attributed to painstaking care in reduction and immobilization. He had looked with privately raised eyebrows on the occurrence of Volkmann's contracture in the hands of his confreres, supposing that it would not have happened under his care. His chagrin can be imagined when, in spite of his best efforts, the contracture occurred in his own case. He concludes, "Désormais, je serais plus indulgent!"

That this mechanism is the proximate cause of Volkmann's contracture is attested by the universal finding of segmentary arterial spasm in all cases in which the artery is surgically exposed during the acute stage. What could not be so easily demonstrated but must logically be considered a key factor is vasoconstriction of the collaterals when the resulting ischemia is total or nearly so. Arterectomy affords all the elements of completely rational treatment because it removes a segment of artery that is not contributing to the circulation but is a source of abnormal sensory impulses, and because it completely interrupts the sympathetic reflex arc both centrally and locally, and thereby most effectively produces vasodilatation of the collaterals.

#### CONCLUSIONS

Volkmann's ischemic contracture should be divorced from its association with supracondylar fracture of the humerus. It is the result of a nearly complete ischemia produced by arterial spasm of the main artery and the collateral circulation.

Interruption of the sympathetic reflex arc is the rational treatment.

Arterectomy gives the best results in stubborn cases.

## CIRRHOSIS OF THE LIVER COMPLICATED BY PERSISTENT RIGHT HYDROTHORAX AND ASCITES

### Report of an Unusual Case

JOSEPH R. FROTHINGHAM, M.D.\*

BOSTON

FROM time to time, cases of cirrhosis of the liver complicated by right hydrothorax have been reported, but the case described below is unusual because of the huge amounts of fluid removed and the great number of tapings both pleural and peritoneal required during the course of the patient's illness. Christian<sup>1</sup> reported a case of hepatic cirrhosis with left-sided hydrothorax requiring a total of nine taps ranging from 800 to 2400 cc. for each tap. Goodman<sup>2</sup> described a case in which an accident had caused a diaphragmatic hernia and in which the extended omentum acted as a ball valve, causing "pleural ascites" in a patient with cirrhosis. Seven taps were necessary, with a total of 20,450 cc. removed. Individual taps yielded 650 to 5200 cc. Sears and Lord<sup>3</sup> described a case of ascites from which "dur-

ing the last two months of his [the patient's] life between sixty and seventy-two quarts were three times withdrawn." Clerc, Debray, Chassigne and Souillard<sup>4</sup> reported a case of long standing cirrhosis requiring one hundred and fourteen abdominal taps over a period of ten years. The frequent tapings and recurring ascites had caused a remarkable distortion of the abdomen. The amounts of fluid removed were not given.

Heart failure has long been recognized as a cause of right pleural effusion. Garvin<sup>5</sup> described such a case in which forty-five taps, averaging 1065 cc. each (total 47925 cc.), were required. For one period of nineteen days, a tap was necessary daily, each one yielding about 1000 cc. The most fluid removed at one time was 1850 cc.

There are many other causes for recurrent hydrothorax, but the case reported below is unusual because the number of taps and the amount of

\*Assistant in medicine Harvard Medical School, junior associate in medicine, Peter Bent Brigham Hospital, captain, Medical Corps, United States Army.

fluid removed far exceed any that I have been able to find in the literature. Even though permission for an autopsy was refused in this case, many diagnostic data, including biopsy, were obtained during the illness, so that the diagnosis is reasonably certain.

### CASE REPORT

H. L. D., a 40-year-old physician, had been in robust health about a year before his first hospital admission (November 4, 1939). At 14, the right hip had been incised and drained for a questionable tuberculosis. The patient had recovered from this satisfactorily. At 28, he had had several attacks of pain under the right costal margin, but none since. The past history was otherwise not remarkable. There was no history of excessive alcoholic intake, although the patient used whisky moderately. The family and marital histories were noncontributory.

For 10 months before admission, the patient had noticed a tendency toward easy fatigability but had no definite complaints. He complained of vague, mild abdominal discomfort, but there was no localized pain of any sort or jaundice at any time. During the 2 weeks before admission, he noted an increasing tendency to easy fatigue and a gradual enlargement of the abdomen, so that his trousers became uncomfortably tight. It was believed that ascites was present, and he entered a hospital for peritoneoscopy and further study. Examination of the blood and urine was negative. The blood Hinton reaction was negative. X-ray films of the abdomen and chest revealed no abnormalities, except for the characteristic abdominal haziness associated with the high diaphragms caused by the ascites. Peritoneoscopy showed "a tiny liver, the entire surface of which was made up of irregular clusters of small nodules"; no biopsy was performed. The patient was discharged on the following day, with a diagnosis of hepatic cirrhosis. The abdominal wound drained slightly for a few days and then entirely healed. The fluid in the abdomen thereafter seemed to decrease until none could be demonstrated. The patient remained at home leading a fairly sedentary life on a high-vitamin, high-carbohydrate regime, but in spite of this he noted increasing fatigue. He lost about 20 pounds in weight during the next 2 months.

On January 6, 1940, the patient noted marked increasing dyspnea, and on examination the following morning he was found to have a massive pleural effusion on the right. He again entered the hospital on January 7. Physical examination showed signs of fluid in the right chest, a barely palpable liver edge and slight icterus. The spleen was not felt. The urine and blood were normal. The serum protein was 7.8 gm. per 100 cc.; the albumin was 3.1 gm. and the globulin 4.7 gm. The benzoic acid (Quick) test showed decreased liver function; the icteric index was over 100. Two thousand two hundred cubic centimeters of straw-colored fluid was removed in two taps. Culture showed no growth. The fluid protein was 0.72 gm. per 100 cc. X-ray examination of the chest after removal of the fluid showed normal lung fields and no apparent cause for the fluid. The patient was discharged after 4 days.

On January 13, he was again admitted because of dyspnea caused by hydrothorax on the right. He remained in the hospital for 12 days, and was tapped 3 times, with the removal of 2400, 3800 and 3300 cc. of fluid. The fluid consistently showed a specific gravity of 1.010 to 1.012, and was of an amber color. No tumor

cells were found in the centrifuged sediment. There was a small amount of bile in the urine. At the patient's request, it was decided to perform any further tapplings at his home, and he was discharged after 12 days. There was still no evidence of accumulation of fluid in the abdomen.

From January 27 to March 1, a right thoracentesis was required every 2 days for relief of dyspnea. The smallest amount of fluid removed at one tap was 1600 cc.; the greatest amount at one time was 4100 cc. The tapping usually yielded 2800 to 3500 cc. Except for one gastrointestinal upset characterized by chills, fever and diarrhea for which he was hospitalized a few days and which subsided spontaneously, he was fairly comfortable when not bothered by dyspnea caused by the hydrothorax. When this was marked, the liver edge was easily palpated, and the edge of the spleen could occasionally be felt. Sediment from the fluid again showed no tumor cells on repeated sections. There were an abundance of eosinophils and mesothelial cells and a few leukocytes, which were interpreted as being a reaction to the frequent tapplings. The serum protein on February 7 was 6.1 gm. per 100 cc.; the albumin was 3.1 gm., and the globulin 4.7 gm. The icteric index was 15. The specific gravity of the chest fluid was usually recorded as 1.007 or less. Venous pressure in the right arm on March 8 was 75 mm. of water.

On March 11, the patient entered the Peter Ben Brigham Hospital for further study. Following complete removal of the fluid in the right chest, a bronchoscopy was passed. No abnormalities of the bronchial tree could be found in the lungs. X-ray studies of the lung following lipiodol injections likewise showed no abnormal findings. A swallow of barium revealed very marked varices at the lower end of the esophagus. There was no evidence of heart disease. Since these studies revealed no evidence of cancer in the pleura, mediastinum or lungs, it was believed that the recurrent right hydrothorax must be associated with the cirrhosis of the liver which had been proved by peritoneoscopy and reduced liver-function tests.

With the exception of 2 days during March, it was necessary to tap the right chest every day. The tapping yielded 1200 to 4100 cc. each, usually about 2400 cc. This meant that the patient was constantly accumulating at approximately 100 cc. per hour in the right chest. The left chest and abdomen remained free of fluid. There was no peripheral edema at this time. There were twenty-five consecutive daily taps.

During April and the first half of May, it was necessary to tap him only every 2 days. The decision to tap the chest was determined by the patient's discomfort. The amount of fluid removed usually averaged around 2800 to 3000 cc. His general condition remained essentially unchanged. During the latter part of May and early part of June, he was tapped every day or every 2 days. From June 16 to July 30, taps were performed daily. The patient was not tapped on July 31. From August 1 to September 30, he was tapped daily. Thus, with the exception of 1 day, the patient required daily right thoracenteses for 106 consecutive days. Most of these procedures were done in the home, but during the latter part of August and in early September the patient felt well enough to travel by automobile to the hospital for the daily chest tap. A total of 1500 to 2500 cc. was the usual yield of each tap.

Because of the apparently endless flow of fluid into the chest and because generalized anasarca was beginning to develop, he was again admitted to the Faulkner Hospital on September 12. On July 12, the serum protein

had been 48 gm per 100 cc with an albumin of 2.4 gm and a globulin of 2.4 gm. On September 17 the serum protein was 6.3 gm per 100 cc, the albumin was 2.6 gm and the globulin 3.7 gm. Since the patient was quite obviously not improving further steps were deemed advisable, to stop the recurring right hydrothorax. It was reasoned that following the removal of 2000 to 3000 cc of fluid from a closed structure such as the chest where there is normally a pressure less than atmospheric there must be an increase in negative pressure. This partial vacuum would tend to suck even more fluid into the pleural space. If, therefore, the fluid were replaced by as much air as necessary to bring the pressures to nearly neutral there would be less tendency for the fluid to reaccumulate in the right chest. Therefore during the next few thoracenteses, approximately the volume of about half the total fluid removed was replaced in the form of air. After this procedure had been repeated about five times, the amount of fluid began to decrease. Associated with this, there was some slight pain on deep breathing on the right side and there was a slight rise in temperature to a maximum of 100.4°F. This gradually subsided. A slight right pleural friction rub was associated with the pain and fever. The amount of fluid aspirated from the chest gradually diminished until on October 7 only 350 cc was removed. Complete removal of the fluid resulted in pleuritic pain, and therefore, a cushion of fluid was left after each tap. This was the last chest tap that was necessary for 4½ months.

The patient was once more discharged home at his own request, and his condition remained essentially unchanged for the next 4 days. However he soon began to notice some swelling of the abdomen and on October 13 his first abdominal paracentesis yielded 5000 cc of straw-colored fluid, which did not clot on standing. The abdominal fluid appeared to be entirely similar to the chest fluid that had previously been obtained. The specific gravity was low, as was the protein content of the fluid.

During the next 2½ months, it was necessary to perform abdominal paracenteses about every 4 to 6 days, to relieve the patient's discomfort. 2000 to 4000 cc was the average yield of each tap. During January 1941 it was necessary to tap the abdomen every other day.

On January 18 the patient was admitted to the Faulkner Hospital for an omentopexy and ligation of the splenic artery. This was undertaken because he had become discouraged with his long illness and because the accumulation of fluid seemed to be rapid. At operation no adhesions were found in the abdomen or about the spleen. The liver appeared normal in size, and the surface was extremely hard and covered with very many bluish nodules. A biopsy of the liver showed microscopically numerous broad, fibrous trabeculations separating the liver substance into irregular lobes. Wherever the portal structures could be identified there was always a broad connective-tissue zone and in addition, an irregularly distributed fibrosis throughout the structure. Definite hyalinization was not found, although there were some areas suggestive of it. The pathologist's diagnosis was cirrhosis of the liver to be regarded as unclassified although suggesting Laennec's type. Because of technical difficulties and the large spleen without adhesions, the splenic artery was not tied. The omentopexy was completed and the abdomen closed without drainage. Eight paracenteses were required while the patient was in the hospital after the operation. He returned home on February 11.

At home it was necessary to tap the abdomen every day or every other day (1500 to 2000 cc each tap) until February 27 when the patient complained of dyspnea and

discomfort in the right chest. Because of the markedly thickened pleura from the previous thoracenteses, it had for several months been nearly impossible to determine the presence or absence of fluid in the chest. However, a chest tap revealed 3000 cc of the usual straw-colored fluid. During the next 4 days daily chest taps revealed a gradually diminishing accumulation of fluid in the right thorax. The abdomen had to be tapped only once during this time, and only 700 cc of fluid was removed. However, with the cessation of the fluid in the right pleural cavity, abdominal paracenteses again had to be resumed every 2 to 4 days. Usually, 2500 to 3500 cc of fluid was removed with each tap. More fluid in the abdomen caused great discomfort. Profuse draining often occurred following abdominal taps and the patient occasionally leaked freely enough through the wound to make tapping unnecessary for an extra day. His condition continued about the same until the end of April. On one occasion in April he again complained of discomfort in the right chest. A thoracentesis yielded about 100 cc of grossly purulent material. A stained smear showed this material to contain innumerable leukocytes and a few staphylococci and streptococci which may have been contaminations no culture was taken. The patient showed little clinical evidence of empyema and it was not necessary to tap the chest again.

During the course of the illness, the urinary output was quite scanty. On examination the urine was usually highly concentrated but otherwise not remarkable. Various diuretics of the mercurial and xanthine derivatives were tried without effect. During March, April and May, 1941, increasing edema of the lower limbs and abdominal wall gradually developed. About April 15, the patient began to notice some ecchymoses of the skin of the legs and trunk. There was also some transient pain in many of the small joints of the body. A few days later, the urine became a muddy wine color, and gross hematuria was noted. The urinary sediment contained many red and white blood cells, and remained so for the duration of the illness.

The course was steadily downhill from then on. Abdominal taps were required every 2 or 3 days. The amount of fluid removed ranged between 600 and 3400 cc. The patient was often very insistent on being tapped, even though it seemed unnecessary at the time. The omentopexy had apparently failed to benefit him.

On May 29, he gradually lapsed into a comatose state, and died on June 1.

#### SUMMARY

A case of cirrhosis of the liver, proved by biopsy and without any clinically demonstrable pathology of the lungs, mediastinum, pleura or heart, is reported, recurrent right hydrothorax necessitated two hundred and eleven thoracenteses for the removal of a total of 467,100 cc of fluid from the right chest. In addition, it was necessary to perform eighty-seven abdominal paracenteses for the removal of a total of 214,580 cc of ascitic fluid. The ascitic fluid and the chest fluid appeared to be similar. With the exception of one day, it was necessary to tap the chest daily for one hundred and six consecutive days. The greatest amount of fluid removed from the chest at any one time was 4100 cc.

## ARGYRIA CONFUSED WITH HEART DISEASE\*

SAMUEL A. LEVINE, M.D.,† AND JASPER A. SMITH, M.D.‡

BOSTON

CYANOSIS is a common finding in both congenital and acquired heart disease. When marked, it is detectable not only in the skin (especially in the most distal parts of the body such as the hands, feet, ears and nose), but also in the mucous membranes and the tongue. Argyria also produces a discoloration of the skin, resulting in a slatelike appearance that may closely resemble the cyanosis of heart disease. Our attention was called to the confusion between these two states by the mistaken diagnoses that were made on several occasions in the last few years. It is evident that the error of overlooking argyria and misinterpreting the discoloration of the skin as being due to the cyanosis of heart disease is a grave one but easily avoidable. Furthermore, the gradual and insidious development of argyria itself is a condition that is entirely unnecessary and preventable. It is because of these simple facts that we believe it appropriate to report the cases discussed below.

It is not our purpose to review the literature on argyria or to go into the mechanism or chemical background of its development. Because of the apparent harmlessness of even marked degrees of argyria, the great majority of cases are never reported. All physicians at one time or another have seen cases, so that the sparse statistical reviews in medical journals can give only a meager picture of its prevalence. We were able to find only one reference in the recent literature in which the presence of argyria led to the mistaken diagnosis of heart disease.<sup>1</sup>

The discoloration in argyria may be of two types: local, such as that around the eyes due to instillation of various forms of silver solutions into the lachrymal ducts, and generalized discoloration of the skin. The latter is apt to result from the absorption of silver through the nasal and gastrointestinal mucosa, such as that following

nasal instillations, or by the injection of silver arsphenamine in the course of antisyphilitic therapy. Gaul and Staud<sup>2</sup> point out that the degree of discoloration depends directly on the extent and duration of the solar or artificial radiation and the amount of silver present in the skin. In following patients receiving antisyphilitic therapy, the authors believed that the clinical detection of argyria occurred when a total of about 8.0 gm. of silver arsphenamine had been given parenterally. It is well known that parts of the body exposed to the light are more profoundly discolored than areas protected by clothing. It is also of interest that the regional intradermal injection of a solution containing 1 per cent potassium ferrocyanide and 6 per cent sodium thiosulfate produces a local and permanent disappearance of the slatelike skin discoloration.<sup>3</sup> In fact, this procedure has occasionally been used therapeutically. The discoloration from bismuth may closely resemble that from silver, but the former is prone to recede spontaneously in three to six months, whereas the latter remains unchanged indefinitely.<sup>4</sup>

## CASE REPORTS

CASE 1. A 7-year-old boy was brought in for examination on January 5, 1934, with the diagnosis of congenital heart disease. He was supposed to have had a bluish discoloration of the skin, especially around the nose and lips, since birth and was treated all this time as a case of congenital heart disease. His father stated that the skin of the rest of the body appeared normal until a few months prior to the visit, and since then the discoloration had involved the entire body. The child otherwise felt well, went to school and played normally, except that he grew fatigued more easily than other children. The pediatrician had always cautioned the parents about the child's activities, and the entire household lived under the constant dread that organic heart disease entailed.

Physical and x-ray examinations revealed a heart of normal size. There was a Grade I apical and basal systolic murmur, but no other abnormalities. Electrocardiograms were normal. The general state of nutrition was only fair, and the urine was entirely normal. There was no clubbing of the fingers. The important finding was the diffuse grayish-blue line of the skin, most marked in the face, but moderate in degree over the rest of the body.

\*From the Medical Service, Peter Bent Brigham Hospital, and the Department of Medicine, Harvard Medical School.

†Assistant professor of medicine, Harvard Medical School, physician, Peter Bent Brigham Hospital.

‡First Lieutenant, Medical Corps, United States Army, Camp Edwards, Falmouth, Massachusetts, formerly, volunteer assistant, Medical Service, Peter Bent Brigham Hospital.

It was this discoloration that had been interpreted as cyanosis and had led to the diagnosis of congenital heart disease. It quickly became evident that the color was quite different from what is seen in organic heart disease. Furthermore, the mucous membranes of the tongue, mouth and conjunctiva appeared normal, if the high degree of discoloration had been due to congenital cardiac cyanosis, one would certainly have expected to find evidence of it in these structures. At this point, on direct questioning of the father, it was learned that since the age of 3 months when the child had a slight nasal cold he had been given almost daily instillations of silver nitrate or Argyrol in the form of drops or spray to prevent sinus infection. In November, 1933, he had been given a half dropperful of silver nitrate solution in each nostril three times a day for a week, and off and on ever since. During the 1st year or so of this silver treatment, the mother was carrying out the doctor's orders. Subsequently, it was more or less her own method of prophylaxis that motivated treatment. However, she had never been told about the potential danger, or to stop the nose drops.

The entire situation was explained to the family and it was made clear that the heart was perfectly normal and that the boy should never use silver in any form again. He has been well ever since, although he continues to show the marked bluish discoloration of the skin.

**CASE 2.** A 15-year-old girl was seen on April 5, 1941 because of a general run down condition, rapid pulse, loss of weight and slight fever of several months duration. Although the physician in charge was not greatly concerned about the situation, there was some suspicion of the possibility of a smoldering rheumatic fever or subacute bacterial endocarditis. She had been seen by numerous physicians because of recurrent slight grippelike infections and a general feeling of asthenia. Many tests, including blood cultures, urinalyses and chemical analyses of the blood, were normal, and x-ray studies were negative. The basal metabolic rate was found to be -18 per cent, and for this reason 1 gr. of thyroid was given three times daily. This was discontinued after a few weeks. More recently, the patient had had a mild sore throat, bilateral otitis media requiring paracentesis, and slight cervical adenitis. Most of the symptoms subsided, although she tended to run a temperature slightly over 99°F. At various times during these few months, attempts were made to have the child get out of bed and resume moderate activities. Each time, the mother and a physician noted that after a little play the pulse would be rapid and what was interpreted as a cyanotic tint to the skin appeared.

Examination revealed a tall, thin, attractive looking girl with a very faint bluish tint to the skin of the face. The heart was entirely normal, except for a very faint apical systolic murmur.

It quickly became apparent that the main problem was a psychiatric one and involved a difficult relation between mother and daughter. Because of the suspicious appearance of the skin, a direct inquiry was made concerning the use of nose drops. It was then learned that for 5 or 6 years the girl had received almost daily instillations of silver nitrate solution. The mother admitted using about 2 or 3 ounces of such solution a year. This had been unsuccessful in preventing colds and sinus infections to which the patient was subject.

When the entire situation was explained to the mother and the family physician, their apprehension concerning the so-called cyanosis was relieved. The importance of the physical aspects of the problem was minimized, and after an appropriate conversation with the child and the mother a better psychologic adjustment was obtained.

The result was that the child resumed her schooling and returned to good health. In this case the disfigurement from the argyria was almost nil, since it could hardly be detected. Its recognition, however, prevented an irretrievable injury to a young girl whose future would otherwise have been greatly handicapped.

**CASE 3.** A 37-year-old woman was seen on March 23, 1938. She complained that she had no pep and that her fingers were blue. She had had both rheumatic fever and chorea in childhood, and during the last several months had noticed that her heart turned over at times. She had been put to bed by her physician because it was thought that she had heart disease. There was no history of dyspnea or pain in the chest.

Examination showed a tall, thin woman with a somewhat slate-like discoloration of the face. The heart was not enlarged, but there was a slight apical systolic murmur. The blood pressure was 134/85. Aside from the murmur, nothing abnormal was found except that the fingers were distinctly blue. Electrocardiographic tracings were normal, and the vital capacity of the lungs was 3400 cc.

It was obvious that this patient had no organic heart disease. The discoloration of the skin was of the type seen in argyria, and with this in mind it was learned on direct questioning that for the previous 5 years she had taken seven drops of a 10 per cent Neosilvol preparation in each nostril every night. This procedure had been carried out on the advice of a nose and throat specialist because of chronic sinus infection.

In this case, the correct interpretation of what the physician regarded as cyanosis led to the diagnosis of no organic heart disease, despite the past history of rheumatic infection.

**CASE 4.** A 50-year-old woman was seen on February 3, 1939, complaining of weak spells with peculiar sensations in the chest, and a feeling as if the blood were rushing to her head. There was no dyspnea or difficulty on walking, and no history of previous rheumatic infection.

Examination revealed a faint grayish blue tint to the skin of the face, and a distinctly bluish discoloration of the base of the nails. The blood pressure was 135/88, the heart was not enlarged, there were occasional extra systoles, and the first sound at the apex and the second sound in the pulmonary area were accentuated. There was a definite, but very short, presystolic murmur at the apex. The vital capacity was 1900 cc., and the electrocardiogram showed a prominent auricular complex, or P wave. The remainder of the examination was entirely negative.

The appearance of the skin aroused the suspicion of argyria, and on further questioning, it was learned that for 4 years the patient had been using a Neosilvol spray twice daily. She stated that she squeezed the bulb of the atomizer four times into each nostril with each treatment. Immediate and complete discontinuance of all silver medication was urged.

In this case, there was evidence of well compensated organic heart disease, but the detection of argyria helped to minimize the gravity of the situation, for there was no evidence of heart failure.

**CASE 5.** A 72-year-old physician was seen on August 7, 1940. During the previous several months, he had noticed increasing shortness of breath, swelling of the ankles and spells of discomfort in the mid-sternum on hurrying.

Examination showed a blood pressure of 185/85, slight enlargement of the heart and a coupled beat, but there were no murmurs. There were a few rales at the right base and considerable soft, pitting edema of the legs. Electrocardiographic tracings showed delayed conduction

time (PR interval, 0.24 second) and coupled beats due to extrasystoles. There was marked slate-like discoloration of the face, but the scleras were not involved.

This patient had congestive heart failure on a basis of coronary-artery sclerosis and slight hypertension. However, the discoloration of the skin was obviously due to argyria, and it was learned that 20 years previously he had begun using nose drops containing either silver nitrate or Argyrol. He continued this more or less regularly for 10 years, but did not notice the change in the skin until a few years after the instillations had been discontinued.

The heart failure progressed despite appropriate treatment, and the patient died in March, 1941. In this case, the marked argyria was an incidental finding, and had no effect on the cause or prognosis of the basic organic heart disease.

### DISCUSSION

In these 5 cases of argyria, mistakes in diagnosis or interpretation of so-called "cyanosis" had previously been made. In 4 cases, faint or marked discoloration of the face or fingers had been regarded as cyanosis of circulatory origin. In all but 1, the fact that nose drops of silver preparations had been used for long periods had been entirely overlooked by the physicians in charge, and had not been mentioned by the patients or their families until direct inquiry was made. In 1 case, the marked slate-like tint, which had been present since infancy, was interpreted as cyanosis of congenital heart disease. In 2 other cases, a milder bluish tinge of the skin brought up suspicions of acquired heart disease. In none of these 3 cases was any evidence of organic heart disease detectable. Of the 2 remaining cases, one patient had a slight, well-compensated mitral stenosis, and the other, heart failure on the basis of hypertension and coronary-artery sclerosis; in both, the "cyanosis" was due entirely to argyria.

It can be readily seen from these experiences that argyria is quite common and often overlooked. It is essential to recognize this fact to avoid serious errors in diagnosis and prognosis. Argyria can naturally be present either with or without organic heart disease. There seems to be no physical handicap that results from even marked argyria, but very great harm can be done to the psyche and personality of the patient from the cosmetic discoloration of the skin. When argyria accompanies organic heart disease, the prognosis is obviously a good deal better than if the condition is misinterpreted as cardiac cyanosis.

No doubt, there is some advantage in using silver preparations for short periods. However, there appears to be no reason to continue the use of nose drops containing silver over the course of months or years when it is realized that the insidious onset of an irreversible and ugly discoloration of the skin may result. Patients and their families should be cautioned very carefully against this danger. It might even be wise to write the expression "do not refill" on all prescriptions containing silver salts.

### SUMMARY AND CONCLUSIONS

Five cases of argyria are presented in which the condition was entirely overlooked for months or years, and the discoloration was misinterpreted as definite or possible evidence of organic heart disease. In one case, it was so marked since infancy that the child was treated for many years as a patient suffering from congenital heart disease. In another, because of bizarre symptoms and slight fever, the possibilities of smoldering and active rheumatic fever or subacute bacterial endocarditis were considered. In another case, because of the past history of rheumatic fever, the possibility of rheumatic heart disease had been entertained. The remaining patients had organic heart disease, but the so-called "cyanosis" was not due to heart failure.

Argyria must be distinguished from the cyanosis of heart or pulmonary disease. It has a peculiar, grayish, slate-like tint, in contrast to the purplish hue of cardiac cyanosis. It is most frequently confined to the parts of the skin exposed to light, the tongue and mucous membranes, which are generally involved in cyanosis due to circulatory disease, being unaffected.

It is evident that argyria is not uncommon, and if it is not recognized, it may lead to a serious error in the diagnosis or management of heart disease or both. Finally, because it is an unnecessary and preventable handicap that is insidious in its development, greater caution must be exercised by physicians in dispensing silver preparations.

## HEMOTHORAX COMPLICATED BY INFECTION WITH *CLOSTRIDIUM WELCHII*\*

JOSEPH P. LYNCH, MD,<sup>†</sup> AND JOHN W. STRIEDER, MD<sup>‡</sup>

BOSTON

WITH the increasing mechanization of modern life, the occurrence of hemothorax and hemopneumothorax resulting from penetrating and nonpenetrating injuries has become so frequent that the conditions are usually sought for and recognized. Moreover, the possibility of infection as a complication of these injuries is generally appreciated, and when it occurs, measures are taken to deal with it. However, infection of a hemothorax by the gas producing micro organisms is a complication not frequently described in civil practice, most of the reported cases having occurred as war injuries. Such infections may be overlooked or the symptoms misinterpreted, since the production of gas by these micro organisms in the hemothorax may simulate hemopneumothorax, with a small but constant bronchopleural fistula

It is the purpose of this paper to discuss this complication of penetrating wounds of the thorax and to report our experience with such a case at the Boston City Hospital

That the condition is rare is apparent from the literature, for various reviews<sup>1, 2</sup> of infection with *Clostridium welchii* do not mention pleural involvement. Others<sup>3, 4</sup> mention it briefly, citing a single case, without further discussion. Elliott and Henry<sup>5</sup> analyzed their findings in an excellent review of 87 cases in World War I. They found that under war conditions 25 per cent of all hemothoraxes became infected, and 44 per cent of these were infected by the gas-producing bacilli. Hence 10 per cent of all hemothoraxes were infected by gas producing bacilli, and 33 per cent of these were fatal. The diagnosis is made by culture and smear of the aspirated fluid, although an odor of hydrogen sulfide may be accepted as very suggestive without the culture. Because the infection may remain localized in one part of the blood clot, a negative culture is some times obtained, therefore, repeated thoracenteses should be done in any suspicious case. Clinically, for the first twenty four to forty eight hours, these patients present a picture of a mildly infected hemothorax, the temperature is usually no more

elevated than that in a simple uninfected hemothorax, but the pulse is rapid beyond expectation.

The cases observed by these authors may be divided into five main types, depending on the predominance of gas production or toxicity: the acute pneumothorax, with overwhelming gas production, which appears clinically as a sudden tension pneumothorax with or without hemorrhage and may progress to a fatality in two or three days; the fulminating septic, in which delirium and jaundice are outstanding and which may be fatal in two or three days; the progressive pneumothorax, whose main feature is a free or localized collection of gas, symptoms and signs becoming obvious after the fourth or fifth day following injury; the progressive toxic, in which symptoms become apparent at the same time as those of the progressive pneumothorax and in which jaundice, restlessness and delirium are prominent, and the chronic, which progresses in the same manner as the usual infected hemothorax, without marked gas formation or toxemia

In treating such infections, these authors have found that radical surgery is most successful. Attempts to avoid opening the thorax proved largely unsuccessful probably because the large masses of infected clot were not removed. Some patients may do well with closed drainage, or the maneuver may be needed as a temporary measure to decompress those suffering severe mechanical disturbances or those who are markedly toxic; as a general rule, however, the open operation is advised

In a brief discussion of this condition, the reports of the Medical Department of the United States Army<sup>6</sup> ambiguously state that "open drainage was generally held to offer the best chance of recovery from this type of pleuritis, though closed drainage would have been more efficacious"

Two other reports of *Cl. welchii* infection of the pleura were found. Bider and Muller<sup>7</sup> report a case in which the infecting organism was introduced at the time of thoracentesis, a method of infection that they consider not uncommon. In the cases reported by these authors, this seems reasonable, but from our experience at the Boston City Hospital we cannot concur in their opinion concerning frequency. They believe that the opening of the pleural cavity and the resulting aeration

\*From the Second Surgical Service, Boston City Hospital

<sup>†</sup>Formerly resident surgeon, Second Surgical Service, Boston City Hospital

<sup>‡</sup>Instructor in thoracic surgery, Boston University School of Medicine; assistant in surgery, Harvard Medical School; associate surgeon for thoracic surgery, Boston City Hospital; visiting surgeon in charge of thoracic surgery, Massachusetts Memorial Hospital

are the most valuable features in the treatment. Porzecanski and Franchi,<sup>8</sup> report a case following a gunshot wound of the chest, in which the patient was treated by rib resection and recovered.

At the Boston City Hospital, many cases of penetrating wounds of the chest are admitted annually, yet this complication has been seen but twice in recent years. On one occasion, a patient with a stab wound of the chest showed *Cl. welchii* in the first culture of the hemothorax fluid two days after the injury. However, he failed to show signs of infection, subsequent cultures of the fluid were negative, and recovery was uneventful. The second case is presented in detail because it showed definite infection of the hemothorax by *Cl. welchii*, with recovery following early open drainage, after the method described by Dolley and Jones<sup>9</sup> for treatment of putrid empyema secondary to rupture of a lung abscess.

### CASE REPORT

T. L. (B. C. H. 1006093), a 34-year-old man, was admitted to the hospital on November 25, 1940, with the complaint of shortness of breath of 2 days' duration. He stated that 5 days before admission he was stopped on the street by two men, who, having been refused money, stabbed him in the left chest. The wound seemed superficial, and he cared for it at home with the help of his wife, who was a trained nurse. He was able to work as a tailor, although 2 days before admission he was moderately dyspneic. This symptom increased until the day before admission, when it was severe enough to keep him in bed. Despite bed rest, the dyspnea increased, and he entered the hospital.

On admission, the patient was acutely ill, anxious, moderately cyanotic and markedly dyspneic. The extremities were cold and moist, the pulse was 120, the temperature was 98°F., and the respirations were 38. The blood pressure was 145/90 and paradoxical between 145 and 120. To the left of the sternum in the 2nd interspace, there was a 2.5-cm. laceration, which grossly appeared clean and through which there was no exchange of air. The trachea was deviated far to the right, and the apex impulse was just to the left of the sternum. There was flatness over the lower two thirds of the left chest, with tympany above this. The breath sounds and tactile and vocal fremitus were absent over the entire left side. Otherwise, the physical examination was negative. The white-cell count was 42,000, and the red-cell count was 4,640,000 with a hemoglobin of 85 per cent. The urine contained many red blood cells and had 3 or 4 white cells per high-power field. The impression on admission was that of a left hemothorax with tension.

A thoracentesis was performed immediately, and 1200 cc. of red, odorless blood removed. Following this, the patient felt much better, the pulse was slower and stronger, and breathing was easier. A specimen of the blood from the chest was sent for a routine culture. For 24 hours, the patient was more comfortable, following the administration of oxygen, morphine and a transfusion of 500 cc. of citrated blood. After this interval, however, he slowly relapsed. The displaced mediastinum, which had come back considerably after the first thoracentesis, was again far to the right, the patient was dyspneic and anxious,

and the pulse ranged between 120 and 130, the temperature varying between 101°F. and normal. During the 2nd day, the patient had repeated slight chills lasting from 5 to 10 minutes and associated with increased anxiety, but no marked rise in the temperature. Blood cultures taken during two of the chills were negative. About 60 hours after admission, the patient's condition seemed as poor as when he was first observed, and thoracentesis was performed again. This time, the fluid was thinner, of a chocolate color, and had a definite odor of hydrogen sulfide. About 1500 cc. was withdrawn, with immediate improvement; the pulse was stronger, the respirations easier, and there were no more chills. In addition, a moderate amount of gas was withdrawn with the changed blood, which had the same foul odor.

A smear of the fluid was made at once, and many large gram-positive bacilli were seen. Investigation of the fluid sent for culture on the day of admission showed that a large gram-positive bacillus had grown anaerobically, and nothing had grown aerobically. This bacillus showed all the characteristics of *Cl. welchii*.

On this evidence, the patient was taken to the operating room, and under local anesthesia a 10-cm. segment of the 8th rib was resected. Before the pleura was opened, the patient was given oxygen by a closed mask, and a small amount of positive pressure was maintained. The pleura was opened for about 2 cm., and the aspirating tip inserted. About 2000 cc. of foul-smelling old blood, together with many clots, was withdrawn. The pleura was then opened the entire length of the incision, a previously prepared large dressing was applied, and the patient was quickly turned on his back. There was very little sucking during this procedure, and none once the patient was on his back. He was returned to the ward in good condition; the respirations were much easier, and the pulse slowed to 100. He was transfused again, started on sulfanilamide, and given *Cl. welchii* antitoxin. He received 120 gr. of sulfanilamide a day for the first 3 days, and then 90 gr. daily was given for 7 days. During the first 3 days, 100,000 units of antitoxin, as well as intravenous fluids and nasal oxygen, was given. After this, the temperature was normal, and the pulse was 90.

The first dressing was done on the 3rd day, with the patient breathing against positive pressure. There was an obviously shifting mediastinum, and much foul discharge on the dressing. A culture was again positive for *Cl. welchii*. This was repeated on the 5th day, when the discharge was gray and foul. On the 7th day, the mediastinum was fairly well fixed, and a catheter was brought out through the dressing for irrigations, with maintenance of the closed wound by the dressing. On the 9th day, the fixation was sufficient to allow the insertion of large drainage tubes and the use of open irrigations. After 2 days, the foul odor had disappeared, and the drainage was serofibrinous. For irrigations, physiologic saline solution and, later, Dakin's solution were employed. On the 15th postoperative day, a culture of the drainage from the pleural cavity was negative for *Cl. welchii*, and they remained negative on all of several subsequent occasions.

The patient had one episode of right-sided chest pain, with an elevation of the temperature to 101°F. This lasted for 4 days and then disappeared. During this time, there were no clinical signs on the right, and a roentgenogram of the chest showed no abnormality on the right. Apart from this, the course was uneventful.

The patient was allowed up on the 32nd day, and was discharged on the 39th day, with a residual empyema cavity of 20 cc. Two and a half weeks following dis-

charge, the wound was completely healed, and the patient had returned to work.

### DISCUSSION

As penetrating wounds of the chest become commoner in civil life, one may expect to see this complication more frequently, and when such injuries occur in military practice the incidence will certainly be greater. Because fresh blood is not a favorable culture medium for *Cl. welchii*, few cases present signs and symptoms of infection within the first twenty-four hours. As the blood ages, however, it becomes an ideal culture medium, and a patient with a chest injury who is apparently doing well may become acutely ill within twenty-four hours. The production of gas by the infecting organism may lead one to believe that he is dealing with a pneumothorax incident to a small perforation, and thus valuable time will be lost if a course of watchful waiting is pursued.

All who have written on this subject, with one exception,<sup>6</sup> agree that the best treatment is early and complete removal of the old blood and clots from the chest by open drainage. Sulfanilamide, x-ray therapy and the specific antitoxin are undoubtedly of benefit, but it is our impression from this case, and from many other cases of anaerobic infection of the pleura,<sup>11</sup> that the aeration accompanying radical open drainage of the infected pleura is of paramount value. The dangers of widely opening, and permitting to remain open, the pleural cavity without adequate mediastinal fixation are appreciated by all thoracic surgeons; however, early open drainage may be necessary as a lifesaving measure and may be performed safely

in these cases by the use of the technic described above. Resection of a long length of dependent rib allows complete drainage of the pleural space, and the large dressing obviates too rapid an exchange of air and the resultant mediastinal flutter. Once the mediastinum is fixed, the treatment is that usually given postpneumonic empyema with open drainage.

### SUMMARY AND CONCLUSIONS

A case of hemothorax complicated by infection with *Clostridium welchii* is presented.

A review of the literature reveals that such a complication is rare in civil practice, but common in the surgery of war injuries.

From the cases reported, and from our experience with this case, we believe that early open drainage is the treatment of choice, but that it should be supplemented with specific antitoxin, chemotherapy and x-radiation.

## MEDICAL PROGRESS

### THE CHEMICAL MEASUREMENT AND CONTROL OF CLINICAL VITAMIN DEFICIENCY\* (Concluded)

WILLIAM T. SALTER, M.D.†

NEW HAVEN, CONNECTICUT

#### NICOTINIC ACID (NIACIN)

THE occurrence of nicotinic acid in concentrates derived from yeast was reported by Funk over a generation ago. Physiologic interest in the vitamin began when Warburg and Christian<sup>65</sup> found nicotinic acid amide as one of the split products of so-called "coenzyme II." Since then, increasing evidence that this substance is essential in enzyme systems having to do with oxidation in tissues has appeared. It occurs in both coenzyme I and coenzyme II, which participate in several well-defined biologic systems concerned with cellular oxidation. When Elvehjem et al.<sup>66</sup> showed that this substance cured black tongue in dogs and later isolated nicotinic acid amide from concentrates of liver extract, its value in clinical disease soon became apparent. Spies, Bean and Ashe<sup>67</sup> have reviewed the role of this vitamin in the treatment of pellagra and associated deficiencies. The material is even essential for bacteria, as shown by several investigators, including Mueller,<sup>68</sup> who worked with the diphtheria bacillus. Because its biochemical function has been known for some time, it is not surprising that chemical determination of this vitamin is well established.

Since this material is necessary for the synthesis of coenzymes I and II, it is apparent that a large amount must exist in tissues and in blood in the combined form as a coenzyme. Of the two factors, coenzyme I, otherwise known as cozymase, is the more easily estimated. Accordingly, studies of this material in blood usually relate to the content of coenzyme I in the erythrocytes. For example, Axelrod, Gordon and Elvehjem<sup>69</sup> showed that soon after large amounts of nicotinic acid were fed to mammals an increase in the coenzyme I (cozymase) content of the erythrocytes took place.

#### *Coenzyme I in Blood and Tissues*

Since certain yeasts specifically require coenzyme I for fermentation, this method of assay has been

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

\*This article comprises a seminar held by the Department of Pharmacology, Yale University School of Medicine, on January 26, 1942. Among the various members contributing, I am especially indebted to my colleague, Professor George R. Cowgill, and to my associate, Dr. Rigby C. Roskelley.

The first part was presented in the April 16 issue of the *Journal*.

†Professor of pharmacology, Yale University School of Medicine.

used, as suggested by von Euler.<sup>70</sup> The determination of coenzyme I can be made simply in the Warburg micromanometric device under carefully controlled conditions. The basis of the method is that, when varying amounts of coenzyme are added to a washed preparation of yeast, the ensuing rate of fermentation is proportional, within certain limits, to the coenzyme I concentration. The measurement involves the rate of evolution of carbon dioxide resulting when the following mixture is allowed to interact: washed yeast, glucose magnesium or manganese ion and hexosediphosphate, properly buffered at the optimal pH.

This method may be applied to extracts prepared from tissue and from the red cells of the blood. Thus, von Euler and Malmberg<sup>71</sup> found that human red cells contained 20 to 35 microgm. of coenzyme I per gram of fresh red cells. Even higher values were found by Elvehjem et al.<sup>69</sup> for the red cells of dogs deficient in nicotinic acid, namely, 60 to 66 microgm. per gram of fresh tissue which is the same as that found in normal dogs. However, Elvehjem and his associates observed that in man the normal value of 20 to 30 microgm. per cubic centimeter of blood might increase to 60 microgm. after the injection of 100 mg. of nicotinic acid a day. This was true of both normal patients and those with pellagra. When this high level had been reached after several days of such therapy, and when the nicotinic acid medication was stopped, the cozymase content of the blood gradually decreased to the normal level in the course of a fortnight. These results confirmed similar results of Kohn.<sup>72</sup> Like blood thiamin, the nicotinic acid seems to be converted into cozymase only in the corpuscles. In other words, it is chiefly the erythrocytes that contribute the enzymic activity of the whole blood.

It is evident, therefore, that the study of the blood is not of great diagnostic help because that of normal and deficient animals does not differ significantly. Thus, Axelrod, Spies and Elvehjem<sup>73</sup> found an average value of 85 microgm. per cubic centimeter of erythrocytes for normal people, as against 69 microgm. in patients with mild pellagra. Similarly, in 5 cases of severe pellagra, values ranged between 70 and 90 microgm. per cubic

centimeter of erythrocytes. It is true, as found by Axelrod, Madden and Elvehjem,<sup>74</sup> that the liver and muscle tissues from deficient animals contain considerably less cozymase than the same tissues from normal animals. In 9 normal subjects, the value per gram of fresh muscle was 382 microgm. of coenzyme I, as against 214 microgm. in 5 patients with severe pellagra. This procedure, however, is not a very practical one under clinical conditions. When nicotinic acid is administered to patients with pellagra, a marked increase in the coenzyme I contents of both the red cells and the muscle occurs, as found by Axelrod, Gordon and Elvehjem and their collaborators.

Vilter et al.<sup>75,76</sup> showed that marked decreases in coenzyme I or II may occur in severe diabetic acidosis or in leukemia, and perhaps also in roentgen-ray sickness and pneumococcal pneumonia. Evidence is presented that the corpuscles merely store the vitamin, rather than actually synthesizing it.<sup>77</sup> These authors, in fact, have found low values in several severe clinical syndromes, as have Justin-Besançon and his associates.<sup>78</sup>

After the intravenous administration of nicotinic acid, the major part of the free vitamin disappears from the blood in half an hour, according to von Euler and Schlenk.<sup>79</sup> Not over one eighth of the total blood vitamin is in the free form normally. Indeed, Kodicek<sup>80</sup> believes that there may be no free vitamin normally. After hydrolysis, the whole blood yields between 1 and 5 microgm. per cubic centimeter. Kühnau<sup>81</sup> found 2.5 to 4.5 microgm per cubic centimeter of whole blood, and Patton, Sutton and Youmans<sup>82</sup> 3 to 5 microgm. Although vitamin-deficient patients tended to have somewhat lower values than normal, this finding was not strikingly consistent. Kohn,<sup>83</sup> who suggested that coenzyme should be expressed per volume of corpuscles, observed the equivalent of 10 to 18 microgm. of combined nicotinic acid per cubic centimeter of human corpuscles (or 50 to 90 microgm. of enzyme).

In summary, it is necessary in determinations of cozymase and nicotinic acid, as in those of the two varieties of vitamin B already considered, to have recourse to urinary studies and particularly to vitamin-tolerance tests.

#### *Nicotinic Acid in Urine*

Methods are now available for determining colorimetrically the urinary excretion of nicotinic acid, nicotinamide and nicotinuric acid, together with other possible derivatives closely related to these substances. Under ordinary circumstances, it is found, as reported by Rosenblum and Jolliffe,<sup>84</sup> that in twenty-four hours approximately 3 to 10 mg. of these substances is excreted by normal per-

sons. Perlzweig, Levy and Sarett<sup>85</sup> observed that in 5 normal human adults on an adequate diet, the average daily excretion of nicotinic acid derivatives (exclusive of trigonelline) was 1 to 3 mg. Furthermore, daily trigonelline excretion on a diet free of coffee was 20 to 29 mg. but approximately 200 mg. when the diet included coffee. As pointed out below, nicotine excretion by tobacco smokers may complicate the analysis if special precautions are not taken.

In the twenty-four-hour urine of well-nourished subjects, Melnick, Robinson and Field<sup>86</sup> found from 1.7 to 29.3 mg. and Patton, Sutton and Youmans<sup>82</sup> 3 to 5 mg. In the urine of patients with advanced pellagra, Vilter, Spies and Mathews<sup>87</sup> were unable to find nicotinic acid. In less advanced cases, Kühnau<sup>81</sup> found urinary concentrations in the lower range of normal, that is, 64 to 105 microgm. per 100 cc.

Rosenblum and Jolliffe<sup>84</sup> also noted that, in a patient with pellagra, urinary nicotinic acid was very low and ultimately disappeared as the patient continued on a diet low in vitamin B complex. When such a patient was put on a diet high in vitamin B complex, however, the urinary nicotinic acid excretion rose within a day to normal levels, and subsequently on a daily intake of 100 mg. of nicotinic acid, excretion reached a peak of approximately 10 mg. in twenty-four hours. Indeed, Perlzweig, Levy and Sarett<sup>85</sup> found that after the ingestion of doses of nicotinic acid as high as 100 to 200 mg., normal adults might excrete 3 to 19 mg. of nicotinic acid derivatives, mostly in the form of nicotinuric acid. This represented a recovery of from 10 to 25 per cent. At the same time, there was a definite change in trigonelline excretion.

Several other investigators have studied the retention of excessive doses of the vitamin in normal subjects and in patients with pellagra. In normal controls, the postprandial administration of 500 mg. of nicotinic acid led to a rapid increase in urinary excretion, according to Melnick, Robinson and Field.<sup>86</sup> This amounted to 22 per cent of the test dose, and was excreted mainly in the form of trigonelline and nicotinic acid. Even with a small dose of 50 mg., Najjar and Wood<sup>88</sup> found that the urinary concentration increased approximately tenfold within four hours. Using oral doses of from 150 to 300 mg. of nicotinic acid or its amide, Patton, Sutton and Youmans<sup>82</sup> were able to recover about 20 per cent of the dose within three hours; after this time, however, no extra vitamin appeared in the urine. Parallel observations on deficient subjects yielded only 3 per cent. With a test dose of 100 mg. of nicotinic acid, Swaminathan<sup>89</sup> obtained the following in-

structive results, expressed as twenty-four-hour excretions:

SUBJECT	NORMAL EXCRE- TION	EXCRETION AFTER TEST DOSE
	mg.	mg.
Well-nourished wheat eaters .	6.8	27.9
Well-nourished rice eaters .	3.2	19.7
Poorly nourished persons	1.3	9.8
Deficiency patients	1.2	5.1

Therefore, the concentration of the vitamin and its derivatives found in the urine is of considerable help in confirming the diagnosis of vitamin deficiency. At present, few determinations are available to indicate whether the so-called "tolerance curve" can be used as a determination of the extent of saturation or unsaturation of the tissues at large. The evidence to date, however, suggests that the vitamin-tolerance curves in these cases, as in those of thiamin deficiency, may be used to measure avidity of the tissues for nicotinic acid.

Several colorimetric methods have been applied to the determination of the nicotinic acid in urine. Most of these are based on color reactions produced by the pyridine ring. Thus, Vilter, Spies and Mathews<sup>87</sup> and Karrer and Keller<sup>90</sup> employed 2,4-dinitrochlorobenzene in the presence of an alkali hydroxide. Similarly, Shaw and MacDonald<sup>91</sup> and Patton, Sutton and Youmans<sup>82</sup> used the reaction with cyanogen bromide in the presence of aniline. Melnick and Field<sup>92</sup> studied the limitations of this method carefully. Ritsert<sup>93</sup> and Pearson<sup>94</sup> and Harris and Raymond<sup>95</sup> have also applied this reaction, the last named using *p*-aminoacetophenone.

More satisfactory is the colorimetric procedure of Bandier and Hald.<sup>96</sup> In their modification, *p*-methylaminophenol sulfate (Metol-Agfa) was allowed to react with nicotinic acid and cyanogen bromide in aqueous solution in the presence of potassium acid phosphate. Under these circumstances, a clear yellow color was obtained that was constant, stable and directly proportional to the concentration of nicotinic acid or of nicotinamide. Several other pyridine derivatives, including trigonelline, failed to give any color. This method has been further modified by Rosenblum and Jolliffe,<sup>84</sup> and by Perlzweig, Levy and Sarett.<sup>85</sup> The method is convenient and is suitable for most clinical research. The final solution may be analyzed chemically with an electrophotometer. Even in urine from heavy users of tobacco or from coffee habitués, this method has given satisfactory results.

Some investigators have used the so-called "V-factor" as a measure of nicotinic acid deficiency. This factor comprises the combined effects of

coenzymes I and II and possibly some other unknown related substances. It is frequently measured by a microbiologic test involving the growth of influenza bacilli. Dorfman, Horwitt and Koser<sup>81</sup> applied this method to human blood and urine, and obtained very consistent results. Likewise, Kohn, Bernheim and Felsony<sup>98</sup> have used the procedure in normal and pathologic subjects, including patients with diabetes, pulmonary disease and pellagra. They found a considerable overlapping of the pathologic and normal patients regarding the content of this factor in corpuscles. Consequently, this method is less desirable for most purposes than the chemical tests mentioned above.

The problem of nicotinic acid metabolism is still complicated by a lack of understanding of the metabolic significance of trigonelline, the betaine of nicotinic acid, and other pyridine derivatives that appear in the urine. Some of these may perhaps be derived from foodstuffs, especially those from seedlike sources. The possibilities are so complex as to make the interpretation of urinary data often difficult. Perlzweig and his associates,<sup>85</sup> moreover, have pointed out that there are considerable differences among several species of animals, and therefore one cannot lean too heavily on collateral animal studies in evaluating observations on man.

#### VITAMIN C (ASCORBIC ACID)

A great deal of work has been done with the physiology of ascorbic acid, otherwise known as cevitamic acid. Consequently, it is possible to mention only a few selected investigations with which I am familiar. For clinical work, the classic methods of bioassay are not practical because they involve the use of many animals. Such methods on rare occasions may be used to check the specificity of chemical methods. For example, occasionally it may be found in the analysis of certain vegetables that a false titer is given by chemical methods as judged by the effect on the scorbutic guinea-pig tooth. Under ordinary circumstances, however, chemical methods are quite adequate for clinical study.

#### Methods

The chief chemical procedures used at present employ modifications of Tillmans's<sup>99</sup> original reagent, the value of which depends on the color loss of an oxidation-reduction indicator known chemically as 2, 6, dichlorophenolindophenol. The use of this indicator has been justified by many observations, such as those of Bessey and King.<sup>100</sup> In this method, under standard conditions, the colored titration solution is rapidly reduced in acid

olution to a colorless compound. The reagent thus serves as its own indicator. Ordinarily, metaphosphoric acid is used as an acid-extractant because it has marked protective properties and is inert toward the indicator.

The basis of this reaction, of course, is the striking reducing effect of the double bond that occurs in the molecule of ascorbic acid between the second and third carbon atoms. Accordingly, the test records only the reduced form of ascorbic acid. Indeed, certain discrepancies have arisen because the oxidized form, which is unstable, is not estimated by this procedure. Some of the complications caused by the presence of other reducing substances have been discussed by Bessey.<sup>101</sup>

In general, it may be said that these difficulties have been largely circumvented in assays of blood and urine. The method for blood is well represented by the procedure of Abt, Farmer and Epstein.<sup>102</sup> In brief, plasma from oxalated blood is treated with metaphosphoric acid to remove protein, and the protein-free fluid is titrated with a standard solution of Tillmans's reagent. This procedure requires 2 cc. of plasma. The final titration is made with a 5-cc. microburette. A stock solution of the dye is made up containing 0.2 gm. per 100 cc. For daily use, it is diluted tenfold and is standardized against small amounts of ascorbic acid.

Various convenient modifications of this method have been made, but Bessey<sup>101</sup> has adapted the technique to photoelectric colorimetry. Furthermore, Findlin and Butler<sup>103</sup> have developed a micro-method that is satisfactory for children and requires only 0.2 cc. of capillary blood. Characteristic values obtained in the clinic may be found in the article by Pijouan and Klemperer.<sup>104</sup>

The determination of ascorbic acid in urine by the use of Tillmans's reagent has been described by many investigators. Convenient methods are those of Harris and his collaborators<sup>105</sup> for the titrimetric procedure and of Evelyn, Malloy and Rosen<sup>106</sup> for the photometric procedure.

Of special interest is the determination of vitamin C in the leukocytes of the blood as described by Stephens and Hawley<sup>107</sup> and more recently by Brandon, Lund and Dill.<sup>108</sup>

#### Blood Content

As stated above, blood analysis is of little clinical value in the determination of the vitamin B complex. The blood ascorbic acid, on the contrary, can yield definite information, although such information must be interpreted in the light of repeated tests. There is a distinct relation between the level of ascorbic acid in the blood plasma and the dietary intake, as shown by many observers. This problem has been studied carefully

by Thyssell.<sup>109</sup> The problem has been studied further by Farmer,<sup>110</sup> who points out that, in general, certain levels may be assigned to characteristic dietary intakes. Thus, if the diet contains less than 15 mg. a day, the blood ascorbic acid level may be expected to be less than 0.2 mg. per 100 cc.; under 30 mg. a day, less than 0.4 mg. per 100 cc.; under 50 mg. a day, less than 0.6 mg. per 100 cc.; under 100 mg. a day, ranging between 0.4 and 0.8 mg. per 100 cc. If the dietary intake is more than 100 mg. of ascorbic acid daily, the blood ascorbic acid may be expected to fall between 1.0 and 2.0 mg. per 100 cc. Wolff, Banning and van Eekelen<sup>111</sup> believe that for optimal nutrition the blood plasma should contain more than 1.2 mg. per 100 cc.

Thus, although some indication may be had of the general range of vitamin nutrition from the level in the blood, it must be emphasized that this is true only when repeated determinations are made or when groups of individual studies are compared. Butler<sup>112</sup> has pointed out that even in persons who are not in dire danger of scurvy the plasma level may fall to nil at times, although the tissues are tolerably well saturated with the vitamin. In other words, the blood is a carrier system for the vitamin, but the equilibrium is not necessarily reversible, so that the blood level may fall even though the tissues still contain considerable stores of ascorbic acid. Thus, in a study of human experimental scurvy, Lund and Crandon<sup>113</sup> found that on a scurvy-producing diet the ascorbic acid level of the blood plasma fell to zero in forty-two days, and that of the white cells in the blood in one hundred and twenty-two days. Nevertheless, the first definite signs of scurvy did not appear for five months, and the symptoms were not severe for six months. Therefore, several investigators in this field do not agree with the conclusions of van Eekelen, Emmerie and Wolff<sup>114</sup> that the degree of vitamin C saturation can be estimated by a single blood determination.

It is true that, in general, there is a straight-line relation between the initial ascorbic acid content of the blood and the total quantity of vitamin needed to saturate the subject. Nevertheless, most investigators prefer to study urinary excretions under standard conditions to determine the need of the patient's tissues for the vitamin. This problem has been discussed by Portnoy and Wilkinson.<sup>115</sup> One source of trouble is the fact, emphasized by Heinemann,<sup>116</sup> that there is a sort of renal threshold for ascorbic acid. Indeed, urinary excretion is relatively slight until the serum level reaches approximately 1.3 to 1.4 mg. per 100 cc., whereupon a sharp rise in urinary out-

put occurs. Moreover, this threshold seems to be influenced by several factors.

### *Urinary Excretion*

It was recognized several years ago that in the presence of ascorbic acid deficiency the daily urinary excretion is low. The chief point of discussion has been the quantitative one of how low the excretion may go without indicating that frank vitamin deficiency is present. Originally, Harris and his associates<sup>117</sup> concluded that if a subject excretes less than 13 mg. of ascorbic acid a day he is probably suffering from vitamin deficiency. For a subject to be optimally saturated with the vitamin, van Eekelen and Heinemann<sup>118</sup> believe that a daily excretion of 40 mg. should be maintained.

Many investigators maintain that a much surer way of testing subjects is to study their retention after a test dose of the vitamin. Various procedures have been used involving different doses. The most frequent is that of administering 5 mg. per pound of body weight as recommended by Harris and his co-workers.<sup>117</sup> The vitamin is ordinarily given by mouth, and within the following twenty-four hours it is expected that a saturated subject will excrete more than half the entire dose. For larger doses, less is recovered, and for smaller doses somewhat more on a percentage basis. Indeed, van Eekelen and Heinemann found that when 300 mg. was given subcutaneously to a saturated patient it was entirely excreted within six hours.

A convenient combination of blood and urine tests has been developed by Kastlin et al.<sup>119</sup> This method involves the intravenous administration of 500 mg. of ascorbic acid and the observation of the blood and urine responses for four hours. The results of blood and urine are plotted in the form of curves. Thus, in a normal person, the blood level rises from the fasting level of about 0.7 mg. to about 7 mg. per 100 cc., and then falls very gradually. During the same time, in the course of four hours, the urinary excretion should be over 40 per cent of the test dose. By contrast, if a deficiency exists, only a slight rise in the blood level above the fasting level occurs, and this rise is variable and is rapidly lost as the tissues take up the vitamin. Simultaneously, the urinary excretion is less than 20 per cent of the test dose in the course of the four-hour period. These curves are, in essence, vitamin-tolerance curves, both for blood and urine. The simultaneous use of these two body fluids increases considerably the reliability of the results.

### *Saturation Tests*

More complicated procedures have been employed in investigations involving the administra-

tion of the vitamin over the course of several days. Gander and Niederberger<sup>120</sup> determined the total quantity of ascorbic acid needed before saturation was reached. This figure is sometimes known as the "saturation deficit." Similarly, standard test doses have been given daily for a number of days until saturation is reached; the number of days required under these conditions has been used as an index of the vitamin C deficiency. Such a method was employed by Jezler and Kapp.<sup>121</sup> In general, however, such methods are too time-consuming to be practicable except in scientific or fundamental clinical investigations.

### *Clinical Applications*

Of course, such tests have additional usefulness in the detection of latent scurvy. Nevertheless, it has become clear as the result of frequent studies by numerous investigators that the dietary is not the only variable involved. Faulkner and Taylor<sup>122</sup> found that in patients with rheumatic and other infections the vitamin C requirement is high and that such patients often lack optimal stores of the vitamin. Pregnancy and lactation also increase the demand for the vitamin. Some of these factors have been reviewed by Robertson<sup>123</sup> and by Perla and Marmorston.<sup>124</sup> Keith and Hickmans<sup>125</sup> have also found marked deficiency of vitamin C in children with rheumatic fever or chronic rheumatism.

In 1927, Aron<sup>126</sup> reported that in scorbutic children cutaneous wounds often failed to heal whereas following vitamin C therapy they healed quickly. Since then, there has been increased interest on the part of surgeons in this problem. Lanman and Ingalls<sup>127</sup> report the case of a six-week-old infant with spontaneous opening of a laparotomy wound in the presence of scurvy. Similar results were obtained by Taffel and Harvey.<sup>128</sup> This problem has recently been studied in man by Lund and Crandon.<sup>113</sup> These investigators concluded that lack of vitamin C is a possible factor in failure of wound healing, particularly in patients with a long and continued avitaminosis. Their observations cast some doubt on the role of ascorbic acid in the production of anemia, however.

### EXTENT OF VITAMIN DEFICIENCY

There is at present considerable disagreement about the extent of malnutrition in the United States. On the one side of the question, one finds the clinical experience of Alvarez<sup>129</sup> and others that gross disease due to avitaminosis is not often recognized in highly reputable clinics. In his inimitable manner, Clendening<sup>130</sup> has presented this side of the case, addressed particularly to readers who have a sense of humor. On the other side, one finds the estimate by Parran<sup>131</sup> that 45,000,000

people in this country do not enjoy optimal vitamin nutrition. This figure is based on the careful study of four thousand American dietaries by Suebeling and Phipard<sup>132</sup>

The problem boils down to what has been called "hidden hunger," which, by definition, can not be diagnosed clinically. How important this state may be in the daily lives of the apparently healthy or of the obviously ill can be answered only when careful functional studies, physiologic and psychologic, are correlated with carefully measured vitamin metabolism. Such a study, indeed, is now in progress at the Lockheed Aviation Plant in Los Angeles as part of a program recommended by the Committee on Nutrition in Industry of the National Research Council.

In the meantime, chemical studies can be applied in the routine clinic to ascertain how great a factor of safety has been afforded by the diet in the individual case. Until it is clear how low a saturation can be tolerated, obviously the safest policy is to ensure liberal replenishment of vitamin stores. In chronic illnesses accompanied by restriction of food, whether spontaneous or enforced, mild vitamin deficiency may lurk unsuspected in the background as a contributory element in the total discomfiture of the patient.

Such data must, of course, be correlated with parallel clinical observations. For example, examination with the slit lamp<sup>133</sup> may be utilized to detect characteristic changes in the corneas of patients deficient in vitamin B<sub>2</sub>, or to detect Bitot spots<sup>134, 135</sup> due to lack of vitamin A. Likewise, the study of other chemical substances, such as pyruvic acid metabolism in vitamin B<sub>1</sub> deficiency, may give specific evidence of disturbed nutrition.<sup>136</sup> At the present time, there is need of many such collateral data before final conclusions can be drawn. Eventually, however, chemical data will afford a convenient parameter by which to integrate many facts drawn from diverse sources.<sup>137</sup> Indeed, Mason and Williams<sup>138</sup> have recently emphasized the utility of such a procedure in clinical studies of thiamin deficiency. This will be particularly valuable in cases of conditioned deficiency, when the nature of the dietary offers little clue to the nutritional status of the patient.

\* \* \*

It may be recalled that convenient methods are available for determining the concentration of the commonly known vitamins in the blood and excreta of human subjects. The use of these procedures has been extended to various types of tolerance and saturation tests. These serve to estimate the extent of tissue stores of vitamin and the avidity with which body tissues retain vitamin. In general, studies of urinary excretion are probably

more significant than the analysis of blood, except in investigations of vitamin A.

The interpretation of the results obtained by these tests requires further statistical study. How impoverished in vitamin must a patient be before he is considered unhealthy? Obviously, a biochemical method cannot answer this question, but it can at least measure the degree of vitamin lack. Already, there is considerable evidence that in Minot's "twilight zone" of subclinical vitamin lack, human efficiency and effectiveness may be greatly impaired. In the impending strain on national resources, this approach will assume particular importance.

# CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

## CASE 28171

### PRESENTATION OF CASE

A seventy-year-old Irish-American was admitted to the hospital because of tarry stools.

About thirteen months before entry, the patient noticed that his stools frequently included small amounts of bright-red blood or streaks of dark blood, or occasionally were frankly tarry. Bowel movements continued regular, without resort to cathartics. There was no pain or distention. The patient visited the clinic of another hospital and had a roentgenologic examination of the gastrointestinal tract that was said to be negative; the symptoms continued, as before. A week before entry, he consulted the clinic of this hospital and was proctoscoped, with visualization of small, high internal hemorrhoids. A roentgenogram of the colon showed an irregular narrowing of the lumen of the midsigmoid, over a distance of 6 cm. The proximal end showed a "slightly intussuscepting" filling defect. The mucosal pattern in this area was abnormal. There were several diverticula of the sigmoid and lower descending colon. The remainder of the colon, the appendix and the terminal ileum appeared normal.

Two sisters of the patient had died of tuberculosis. When he was between twenty and thirty years old, the patient had several "nervous breakdowns" characterized by personality disturbances and dipsomania. For many years after this, he experienced occasional nausea and vomiting after breakfast. Five years before entry, he had hemorrhoids removed at another hospital. Three years later, after a period of urinary frequency terminating in an episode of acute retention, the patient had a two-stage prostatectomy, also in the other hospital. At about this time, he developed an eruption on the left cheek. A year later, he consulted the clinic of this hospital. Biopsy of the lesion, three months before entry, showed carcinoma of undetermined type. In the following month, 4300 r of roentgen therapy was given to the cheek, with resultant regression of the lesion.

On admission, the patient appeared well preserved, plethoric and in good health. A mottled scar, 2 cm. in diameter, lay on the left midcheek. The heart and lungs were essentially normal. The abdomen was soft, with an elongated mass

in the left lower quadrant that could be rolled between the examiner's fingers. There were no other palpable masses. There was a small hernia at the site of a midline suprapubic old operative incision, and a right direct inguinal hernia. Rectal examination was negative.

The blood pressure was 240 systolic, 120 diastolic. The pulse, temperature and respirations were normal.

Examination of the blood showed a red-cell count of 4,900,000 with 90 per cent hemoglobin, and a white-cell count of 7800 with 66 per cent polymorphonuclears. The urine was normal.

A roentgenogram of the chest showed only tortuosity of the aorta, and old calcified tuberculous foci in both upper lobes. An electrocardiogram showed changes consistent with either hypertensive or coronary heart disease.

On the third hospital day, cecostomy and appendectomy were performed under local anesthesia. There was little postoperative reaction, and the cecostomy tube drained well. A roentgenogram of the large bowel showed marked delay in passage of barium above the abnormal area noted in the previous examination.

On the fourteenth hospital day, a second operation was performed.

### DIFFERENTIAL DIAGNOSIS

DR. EDWARD L. YOUNG: This is a case in which we must discuss the differential diagnosis of a tumor of the midsigmoid causing partial obstruction. The possible causes are many, the probable causes few. This patient had a fairly normal bowel habit, no changes being apparent in the stools except for the presence of blood, so that we can almost surely throw out any ulcerative form of colitis. The things that must be considered in the order of probability are: cancer and diverticulitis, infectious granulomas and the rare tumors, such as sarcoma or some form of benign tumor, such as lipoma. Also, we might consider intussusception as a mere possibility. Although chronic intussusception does exist, it is generally of the ileocolic variety, it is very rare at this age, and its presence does not cause bright blood, so that I think we can discard that diagnosis. Tuberculosis is a possibility. To make us consider tuberculosis is the fact that the x-ray examination showed old tuberculosis in the patient's lung. Tuberculosis of the bowel is usually a disease of young people. Furthermore, tuberculosis usually involves the ileocolic region, and is generally, though not necessarily, accompanied by a certain degree of activity of the pulmonary tuberculosis. In this case, the disease was on the left; it was not the ulcerative but the hyperplastic type because of the tumor

felt. I believe that we can discard tuberculosis. Because of their rarity, we need not consider infectious granulomas of other origin.

The case boils down, then, to a differential diagnosis between carcinoma and diverticulitis, both of which could fit the picture. We used to be taught that patients with diverticulitis rarely bled and that when either gross or microscopic blood was present we should always look for some other disease. However, we now believe that at least 20 per cent of the patients with diverticulitis do bleed at some time or other, although it is not common to have so much bleeding as this patient had. Moreover, a subacute perforation with an infectious area about the bowel could cause such a tumor as that felt in this case, and we do know that diverticula were visible on the x-ray films. Carcinoma, of course, can fit this picture very well. We must remember, moreover, that both could exist in the same case. I believe, however, that when this is so there is no connection between the two. Is it possible, then, to differentiate these two lesions? I think that the x-ray films are the best evidence we have, and I should rely largely on what the radiologist says. If the statement "slightly intussuscepting" means anything, it certainly suggests a proliferative type of growth of the inside of the bowel. What about it, Dr. Hampton?

DR. AUBREY O. HAMPTON: I think the report reads a little more obviously like tumor than the films do. In the large one, practically everything is obscured by what appears to be diverticulitis, and there is a good deal of spasm in the sigmoid. This second film must be the one from which they concluded that the mucosa was abnormal. The area of involvement is only about 3 or 4 cm. I think this may be what they meant by the intussuscepting defect, but I do not believe that we have any evidence of intussusception. We have evidence of diverticulitis and absence of mucosa over a distance of 4 cm., with an apparent filling defect.

DR. YOUNG: Should you be willing to make a diagnosis on the x-ray films as they stand?

DR. HAMPTON: I think I should, with a little reservation.

DR. YOUNG: If we may believe that diagnosis, what is the treatment? With the two in our mind, the main thing to do is treat it as cancer because I do not believe the surgeon exists who can feel of this with his hand in the abdomen and be sure which it is. Therefore, it must be treated as a cancer. In this seventy-year-old man, the blood pressure was 240, and the justification of any operation is that the hazard of operation, in the last analysis, is no greater than that of the condition one is operating for; the outcome, if the

condition is cancer, is certain death. So that or is justified in going the distance. I believe the evidence points more strongly to cancer than to diverticulitis.

DR. REED HARWOOD: Did the laboratory tests show occult blood in the stools?

DR. TRACY B. MALLORY: Yes; on the single specimen examined.

DR. CHESTER M. JONES: It certainly is most unusual to have that much blood from diverticulitis, although one does see some blood occasionally.

DR. MALLORY: One interesting sidelight is that during the entire period covered by this story the patient was being treated in our tumor clinic for carcinoma of the cheek. He never told anyone in this hospital, however, about the abnormality of his stools. He went to another hospital with that story, and the first x-ray examinations were done there and were negative.

DR. YOUNG: Do you mean that they did not spot the diverticula?

DR. MALLORY: So the report says. It is hard to believe.

DR. HAMPTON: I do not believe that they missed them.

DR. HARWOOD: It seems unusual to have a normal red-cell count and hemoglobin with bleeding for thirteen months.

DR. CLAUDE E. WELCH: The patient was not the most intelligent Irishman I have seen, and we doubted much of the story. There is no question that he bled a good deal, however. We thought he had carcinoma of the colon on the basis of the first x-ray report. But, in view of the visible diverticula, we had enough doubt about the situation to do a second barium enema, twelve days after the first, to determine whether there had been any change. The report that came back from that was "absolutely no change," and we justifiably thought that we had additional evidence in favor of the existence of two lesions—diverticulitis and carcinoma. At the time of the second operation, it was noticed that the patient had a tremendous mass of adhesions in the lower pelvis, large enough for us to be tempted to say that the lesion was inoperable. With a little difficulty, the lesion was resected, and anastomosis done. The patient had a perfectly uneventful postoperative course.

DR. HAMPTON: The way the case is building up, I am sure that Dr. Young and I will be wrong. The films, however, certainly suggest that the patient had a carcinoma.

DR. YOUNG: I was going to ask if you would "stick your neck out" too.

DR. HAMPTON: I looked at all the films and did not think of it until I saw the last spot film,

which looks very much like carcinoma. The other films look like diverticulitis.

DR. YOUNG: The question of whether the mucosal layer was gone is important, and I assumed you said it was.

DR. HAMPTON: It appeared to be. I cannot be certain. One can have edema or constriction from outside pressure or infection, and the mucosa will appear to be abnormal.

DR. YOUNG: Did you feel the mass at the time of the first operation?

DR. WELCH: No attempt was made to palpate it at the time of cecostomy.

#### CLINICAL DIAGNOSIS

Carcinoma of sigmoid.

#### DR. YOUNG'S DIAGNOSIS

Carcinoma of sigmoid.

#### ANATOMICAL DIAGNOSIS

Diverticulitis of sigmoid.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The resected specimen showed multiple diverticula, several of which were inflamed. There was no evidence of tumor. The mucosa between the diverticula was markedly edematous, producing a pseudo-polypoid appearance, which accounts for the abnormal mucosal pattern in the films.

DR. HAMPTON: Was there an abscess?

DR. MALLORY: No frank abscess.

DR. HAMPTON: No perforation?

DR. WELCH: No.

### CASE 28172

#### PRESENTATION OF CASE

*First admission.* A fifty-six-year-old housewife was admitted to the hospital because of cramping lower abdominal pain and vomiting.

The patient had been constipated for many years and on occasion used various laxatives, but she had no pain or other symptoms referable to the bowels. Three days before entry, following an upper respiratory infection of several days' duration, there was a fairly sudden onset of severe cramping pain, extending across the lower abdomen from the right lower quadrant. The patient took a proprietary laxative and vomited almost immediately. Several additional doses of the medicine were then taken, with subsequent partial abatement of the cramps. On the day preceding admission, there was further vomiting, and the cramping became severer despite further doses of laxatives

and hot rum punch. On the first day of the illness, the patient had two or three bowel movements, on the second day one or two, on the third day four, and on the day of admission none. None of the movements included evident blood.

Six years before entry, the patient had a complete hysterectomy, a bilateral salpingo-oophorectomy and an appendectomy performed at another hospital, with the finding of leiomyomas of the uterus, chronic cervicitis and bilateral early cystadenomas of the ovaries. Four years later, mastectomy was performed in the same hospital, in treatment of a benign intractable papilloma. The next year, the patient had a sacral laminectomy at this hospital because of backache and swelling over the lower spine. Two paradural cysts of unknown type were drained, but not removed or biopsied. Aside from these difficulties, the patient was in good health.

On admission, the patient appeared well nourished but acutely ill, with flushed face, dry, coated tongue and warm skin. The nose and throat were mildly injected. The lungs were clear. The heart was normal. The abdomen was distended, with hypoactive peristalsis. An area of erythema over the left lower quadrant suggested a burn from a hot-water bottle. There was generalized abdominal tenderness, most marked in the left lower quadrant, where voluntary rigidity was also most marked. There was rebound tenderness all over the abdomen, which was referred to the point in the left lower quadrant that was most tender on direct pressure. Pelvic examination showed boggy induration of all sides of the vagina, without definite masses. Tenderness was somewhat more marked on the left. Rectal examination showed induration high on the anterior wall of the rectum.

The blood pressure was 140 systolic, 80 diastolic. The temperature was 103°F., the pulse 100, and the respirations 20.

Examination of the blood showed a white-cell count of 15,050, with 80 per cent hemoglobin. The urine was normal. The blood chemical findings were essentially normal.

On the fifteenth hospital day, a roentgenogram of the large bowel showed prompt filling of the rectum and distal sigmoid. At the junction of the middle and proximal thirds of the sigmoid, there was a more or less annular area of narrowing, conical in its distal portion, causing almost complete obstruction. There was no definite edge to this lesion, suggesting an extrinsic pressure defect. A small pouch just above the area of narrowing was consistent with a small diverticulum.

On the twenty-fourth hospital day, a Devine colostomy was performed. Exploration of the abdomen showed a mass in the pelvis apparently

continuous with the sigmoid, which felt irregular, edematous and fixed. Adhesions were present in the region of the old laparotomy scar. There was no evidence anywhere of metastatic disease. Following operation, there was some fever, which slowly subsided. The patient was discharged on the twenty-fourth postoperative day, with the colostomy working well.

*Second admission* (eleven months later). The patient continued well, following discharge. There was no pain, fever, cramping or rectal bleeding. A follow-up roentgenogram showed obstruction of the sigmoid, quite similar to that noted in the previous examination. Barium introduced through the colostomy opening into the distal segment of the colon passed readily to the area of obstruction, outlining a few small diverticula just proximal to the obstruction.

On re-entry, physical examination was essentially as before, except that the abdomen was free from tenderness and distention. The rectum admitted a proctoscope to a distance of only 13 cm., owing to angulation of the bowel. The mucosa appeared edematous, injected and friable.

Examination of the blood showed a white-cell count of 8800. The blood chemical findings were normal.

An intravenous pyelogram was negative.

On the fifth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. HENRY H. FAXON: I can save considerable time by referring to the discussion that Dr. Young has just given. Here, again, we have a differential diagnosis of a lesion in the sigmoid with the same possibilities that he has already mentioned. Before I heard the final outcome of his problem, I had planned to emphasize what Dr. Jones has said: that bleeding is most uncommon with diverticulitis. On the basis of the bleeding in the preceding case, I should have been extremely skeptical that the lesion was due to diverticulitis.

My discussion of this case is based on the same premise that the absence of gross blood is suggestive of a diagnosis of diverticulitis. The disease that the patient apparently now has is obviously in the sigmoid. The outstanding points, it seems to me, are that the two acute episodes were of short duration, that especially the first of these was marked by the manifestations of infection with an elevated temperature and so forth, and that nearly a year elapsed between the two hospital entries. Let us see now if the X-ray Department can help us.

DR. AUBREY O. HAMPTON: The picture suggests something surrounding the bowel at the point of

maximum narrowing. I believe that the mucosal folds are intact. They could be absent on one side, but I shall stick to the record that the lesion was probably extrinsic and that a diverticulum was present.

DR. FAXON: A possible undetected endometriosis affords the only connection between the present lesion and that for which the previous hysterectomy was done. It is not uncommon to find the large bowel involved in endometriosis, but since the ovaries had been taken out at the time of the operation six years previously, it would be surprising if endometriosis played any part in the present involvement of the large bowel. We have definite information from the operative note that seems to exclude cancer. If a malignant lesion was present, it was at any rate unrecognized by the operator. Furthermore, eleven months went by before the patient again appeared with the same symptomatology and the same type of picture.

What the operation for paradural cyst was and what significance can be attached to it, I frankly do not know. I do not believe that it played a part in the present bowel disease, but I may be overlooking a good lead in merely dismissing it.

I believe that one of the diverticula actually ruptured and gave rise to infection about the bowel, and that with the sidetracking afforded by the Devine colostomy the inflammation quieted down. Many such inflammatory masses are hard to distinguish from cancer at operation, as Dr. Young has said. They often subside but, if due to diverticulitis, often recur in similar fashion. I believe that the primary lesion in this case was diverticulitis.

DR. HAMPTON: What was the X-ray Department's conclusion?

DR. TRACY B. MALLORY: They did not say anything more than "inflammatory mass." It is probably safe to assume that they were thinking of diverticulitis.

DR. HAMPTON: That is the implication I meant to leave.

DR. CLAUDE E. WELCH: Is that not very unusual for that length of time?

DR. HAMPTON: It seems that diverticulitis should have improved more than this patient's had.

DR. WELCH: Especially with colostomy.

DR. HAMPTON: And especially since, at the first examination, the bowel looked somewhat flexible. It did not look like the chronic scarring of diverticulitis.

DR. HOWARD ULFELDER: I performed the first operation in this hospital, and of course responsibility for diagnosis could not rest on that procedure.

It was done merely to defunction the large bowel. I thought I overstepped myself at the time in exploring the patient as much as I did, in view of the very recent pelvic sepsis. However, I did exclude cancer to the best of my ability. I found a well-fixed mass in the pelvis and a normal liver, and then did a transverse colostomy.

#### CLINICAL DIAGNOSIS

Diverticulitis of sigmoid.

#### DR. FAXON'S DIAGNOSIS

Diverticulitis of sigmoid.

#### ANATOMICAL DIAGNOSES

Carcinoma of sigmoid.

Chronic inflammation, with abscess formation in mesentery.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: At the second operation, the findings were quite different. At that time, it was obvious that the pelvis was quite well filled with carcinoma. It was also clear that the disease was incurable; however, it was decided that enough relief of symptoms could be obtained by resection to justify such a procedure. There was an inflammatory mass in the mesentery, and to a considerable extent the conclusions of the radiologist were justified; but it was a carcinoma, not a diverticulum that had undergone a subacute perforation.

DR. HAMPTON: How big was the carcinoma?

DR. MALLORY: It was an annular lesion about 3 cm. in diameter.

DR. HAMPTON: I cannot find it in the x-ray films.

## MALPRACTICE INSURANCE FOR PHYSICIANS IN MILITARY SERVICE

A LETTER in this issue of the *Journal* brings up the question whether a physician in military service should carry malpractice insurance.

In an editorial, "Malpractice Actions against Army Medical Officers and Examining Physicians for Local Selective Service Boards," in the September 13, 1941, issue of the *Journal of the American Medical Association*, it was stated that the Judge Advocate General of the United States Army had ruled, on May 1, 1941, that members or prospective members of the Army are entitled to the same civil rights of action between one another with reference to suits for malpractice or negligence as they would have in civil life. Hence, a man in military service who has been

attended by a medical officer in line of duty or a selectee who has been examined by a physician attached, either in a civilian or military capacity, to a selective-service or induction board may bring suit for alleged malpractice. Although no official statement has been offered by the Judge Advocate General of the United States Navy, it seems likely that the same ruling would be made. Furthermore, several of the commercial companies that offer malpractice insurance have recently announced a new type of policy, which covers physicians who are in military service.

Whether this type of insurance is necessary is a matter that each medical officer must decide. It is obvious that all physicians who serve in a civilian capacity on selective-service or induction boards are protected against malpractice suits if they carry standard policies, — and if they are not insured, they are running no more risk than they do in everyday practice. In addition, the chance that suit will be brought by a man in active military service is exceedingly unlikely, — as shown by the relatively low rate of the military policy, — and if action is taken, it has been the custom to transfer the case to a federal court and to furnish the defendant with federal counsel designated by the Department of Justice. In spite of the fact that there is, at present, no legal provision for the Government to pay the claim or to reimburse the defendant if a judgment favorable to the plaintiff is rendered, at least one branch of the service — the Selective Service System — has intimated that it would make an attempt to protect him from financial loss, even if this required a special act of Congress. Although the possibility of personal loss by a well-trained medical officer seems extremely unlikely, the risk does exist and should probably be covered by a military policy.

## THE KENNY METHOD OF TREATMENT OF INFANTILE PARALYSIS

Miss Elizabeth Kenny, a nurse from the hinterland of Australia, developed a treatment for poliomyelitis that is now being widely used in this country. She has carried on her work in America

under the auspices of the National Foundation for Infantile Paralysis, having demonstrated her method before a qualified group of observers at the University of Minnesota. The reports now available suggest that the results of her treatment of patients both in the acute and in the chronic stage of poliomyelitis are unusually satisfactory. In many cases, she has prevented the development of contractures and deformities, and in general, the muscles of these patients have shown less than the usual amount of paralysis. In other words, most observers who have visited the clinic established in Minneapolis have come away impressed by the results obtained. In view of the success of her treatment, plans are being made to publish the essential facts, as well as a discussion of Miss Kenny's ideas, in a pamphlet to be issued by the National Foundation for Infantile Paralysis. Until this is available, those who are interested should consult Miss Kenny's book.\*

Her account, however, is difficult to understand, since many of her arguments require definitions of the terms that she uses. For instance, the word "spasm" is used in a manner foreign to current medical understanding. She speaks of spasm as a primary symptom of paralysis, and considers fibrillation, twitching, hyperirritability to stretching and a tonic state of contraction to be signs of spasm. She believes that spasm is responsible for the paralysis and also for the malposition of the limbs. Flaccid paralysis as a primary symptom of the disease is denied by Miss Kenny, she contends that muscles cannot move, not because they are paralyzed, but because they are overstretched by the opposing group of muscles in spasm. Miss Kenny uses two other confusing terms, "inco-ordination" and "mental alienation." Inco-ordination, according to the interpretation, depends on muscle spasm and is the result of the spreading of impulses to other muscles because the muscle involved exhibits pain or is unable to move. Inco-ordination may also be caused by ineffective contractions in the affected muscles. Mental alienation, the third term, deals with the inability

of muscles to function because of the spasm and pain due to the contraction of opposing groups or because of the interruption of pathways from processes in the central nervous system not permanently destroyed. These three terms, as will readily be appreciated, are almost foreign to medicine, and without Miss Kenny's definitions of them, one cannot even attempt to understand her method and reasoning.

Whatever the theoretical considerations concerning Miss Kenny's work, there can be little doubt of the practical value of her treatment. Although not particularly easy to understand or simple to carry out, the method can be learned in a year by any well trained physician or physiotherapist. It consists essentially of continuous attention from a highly trained staff of attendants, with the absence of manipulation, all appliances or any form of treatment that will increase the spasm in the affected muscles. Massage in all forms should be avoided. Pressure from the bedclothes, unnecessary handling and pressure from casts and splints, according to Miss Kenny, increase spasm. The spasm itself is treated by hot fomentations applied in a careful and routine manner. Moreover, she does not believe in the testing of muscle strength in acute poliomyelitis, since these determinations tend to increase spasm and pain and therefore to retard recovery. When pain and spasm have been overcome by hot fomentations, active therapy is started. The techniques of muscle re-education developed by Miss Kenny call for an intimate knowledge of muscle anatomy and function. Thus, the excellent end results seen in her cases are brought about through careful treatment by use of physiotherapy of a specialized nature directed toward inco-ordination and alienation, as well as through the proper application of heat during the stage of spasm.

The Kenny method completely revolutionizes modern ideas regarding the treatment of acute poliomyelitis. Muscle testing, splinting, avoidance of overstressing, absolute rest and many other procedures are largely overthrown, and additional modifications will naturally follow.

\*Kenny E. *The Treatment of Infantile Paralysis in the Acute Stage*. 285 pp. Minneapolis and St. Paul: Bruce Publishing Company, 1941.

If the technic is adopted, the physician, whether he is a pediatrician, orthopedist, neurologist or clinician, must begin treatment of the affected muscles on the very first day of the disease: in most cases this means starting intensive therapy in a hospital for infectious diseases. Furthermore, treatment must be continued unremittingly until all power that is possible returns to the affected muscles.

## MEDICAL EPONYM

### OPPENHEIM'S SIGN

Hermann Oppenheim (1858-1919), of Berlin, presented a discussion, "Zur Pathologie der Hautreflexe an den unteren Extremitäten [On the Pathology of the Skin Reflexes in the Lower Extremities]," in the *Monatsschrift für Psychiatrie und Neurologie* (12: 421-423, 1902). A portion of the translation follows:

If the handle of the percussion hammer is drawn down along the inner aspect of the lower leg (about at the posterior margin of the tibia or even beyond it) in healthy persons, there will be seen either no motion of the foot and toes, or a plantar flexion. . . . In patients presenting the symptom complex of spastic paraplegia or hemiplegia, the maneuver described usually results in a reflex muscular contraction causing an extension of the great toe, and either adduction or abduction of the foot.

### COMMITTEE ON MATERNAL WELFARE

CASE HISTORY: HYDRAMNIOS FOLLOWED BY POST-PARTUM HEMORRHAGE, HYSTERECTOMY AND DEATH

A thirty-seven-year-old essential primipara (there had been one spontaneous abortion) who had had excellent prenatal care developed an upper respiratory infection for which she was hospitalized at the very end of her pregnancy. There undoubtedly was some mistake concerning dates, since the record states that labor did not set in until five weeks after the estimated date. There had been no complications during pregnancy; the blood pressure and urine were normal, and the past history was irrelevant. A diagnosis of hydramnios and anencephalus was made before labor. Although it is not so stated, an x-ray film had in all probability been taken on which this diagnosis was based. The upper respiratory infection was not accompanied by fever. Labor

started spontaneously by the rupture of the membranes, and eighteen hours later the patient was delivered normally, with the aid of cleidotomy. The weight of the baby is not given, but presumably it was a large child. A second-degree tear of the perineum was sustained and immediately repaired. The placenta, delivered normally, was followed by tremendous hemorrhage, and the uterus was packed. The patient was given four transfusions. Since the uterus continued to bleed, an abdominal suprapubic hysterectomy was performed eight hours after delivery. In spite of three additional transfusions, death occurred twelve hours later. No autopsy was performed.

\* *Comment.* Hydramnios, with the resulting overstretching of the uterus, has always been considered a possible cause of post-partum hemorrhage. For the same reason, the stretching that accompanies twin pregnancies may also result in bleeding. In all such cases, the fundus should be very carefully watched after delivery; sometimes the intravenous use of ergotrate is of value in combating atony. All that could possibly have been done for this patient was done. The fatality merely emphasizes the occasional seriousness of post-partum hemorrhage and the ever-present possibility of the need for hysterectomy and for repeated transfusions.

### DEATHS

CRANE — CLARENCE CRANE, M.D., formerly of Boston, died April 13. He was in his seventy-second year.

Born in Salem, Oregon, Dr. Crane received his degree from Boston University School of Medicine in 1900. He was assistant professor of surgery at Boston University School of Medicine from 1900 to 1921, and staff surgeon of the Massachusetts Memorial Hospitals. He was a former member of the Massachusetts Medical Society and the American Medical Association, and a fellow of the American College of Surgeons.

He is survived by his widow, three sons, and two daughters.

PERRY — SHERMAN PERRY, M.D., of Winchendon, died April 20. He was in his sixty-fourth year.

A native of Passaic, New Jersey, Dr. Perry received his degree from Harvard Medical School in 1907. He served on the staffs of the Worcester City, Boston Children's and Tewksbury State hospitals and was a former president of the Worcester District Medical Society. He was a member of the New England Obstetrical and Gynecological Society, and a fellow of the American Medical Association.

His widow survives him.

WALKER — JOHN B. WALKER, M.D., formerly of Boston, died April 13. He was in his eighty-third year.

Dr. Walker received his degree from Harvard Medical School in 1888. He was formerly on the staff of the Boston City Hospital and was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, two sons and two daughters.

## WAR ACTIVITIES

## CIVILIAN DEFENSE

HOSPITALS TO BE REIMBURSED FOR CARE  
OF CIVILIAN CASUALTIES

Payment for temporary hospitalization of civilians injured as the result of enemy action has been made possible by a recent agreement between Administrator Paul V. Nitte of the Federal Security Agency and Director James M. Landis of the Office of Civilian Defense. The funds have been allocated to the United States Public Health Service by the Federal Security Administrator from funds made available to him from the President's emergency fund. A joint memorandum embodying the details of the program has been issued by Surgeon General Thomas Parran of the United States Public Health Service and Dr. George Brehm, chief medical officer of the Office of Civilian Defense.

The plan provides that all hospitals caring for civilian casualties in the event of air raids or other enemy action will be reimbursed by the federal government at a rate of \$175 a day. This is the rate of reimbursement established by the Federal Board of Hospitalization for federal beneficiaries in government hospitals and may be changed as conditions require, it was stated.

Any hospital in the Nation, voluntary or governmental, may be used as a casualty receiving hospital in the Emergency Medical Service established by the Medical Division of the Office of Civilian Defense. In addition certain hospitals and other institutions in safe areas may be used as emergency base hospitals for casualties or other patients whom it may be necessary to evacuate from urban hospitals in exposed areas. The new agreement provides that federally owned equipment may be loaned to the base hospitals and that their staffs will be supplemented by physicians of the region who will be commissioned in the reserve corps of the United States Public Health Service. It is emphasized that management and control of all hospitals, both local casualty receiving hospitals and emergency base hospitals, will remain the responsibility of the local or state authorities.

In the establishment of emergency base hospitals, emphasis will be placed on the relative safety of the area and the availability of existing hospitals and other institutions. Hospitals are now being surveyed for this purpose and will be classified on a basis of size, equipment and standards of operation.

It is proposed to begin immediately the organization of medical staffs for future base hospitals as hospital units affiliated with casualty hospitals similar to the affiliated general hospitals of the Army. The physicians, surgeons, specialists and dentists who are to be commissioned in the Public Health Service Reserve for service in these hospitals will receive rank, pay and allowance equivalent to those of the Medical Corps of the United States Army. They will be selected from older age groups, from physicians with disabilities that make them ineligible for military service and from women physicians. So far as possible, they will be assigned to service in the regions in which they live. Because they are to function as balanced professional staffs, they will be recruited from the staffs of civilian hospitals and cleared through the Procurement and Assignment Service.

## MISCELLANY

TUBERCULOSIS IS FOUND  
WHEN LOOKED FOR

The gap between proved knowledge and effective action based on that knowledge is nowhere more glaring than in our fumbling efforts at control of the commonest of the infectious diseases.

We know that the time lost from the common cold would build hundreds of the planes we now need so much. Yet, the simple prophylactic measure of isolating all those with colds in early stages is applied routinely to a few school children only.

This failure to co-ordinate knowledge and action is also all too common in our efforts to control and eradicate tuberculosis.

That tuberculosis can be found and is most easily cured in the stage before symptoms appear is an axiom that has grown true with repetition, yet the great majority of people fail to translate this into the action that will safeguard themselves and their families from this disease.

But what are the facts? In four years, the deaths from tuberculosis surpass the number of those killed in all the wars the United States has ever fought. If the losses of one year from tuberculosis could be attributed to enemy action, the nation would be shocked with grief and vow vengeance at any cost. Yet the slow undramatic dribbling away of lives goes on day by day, although proof has been added to proof that this can be stopped.

An example is provided by colleges and universities. Into their doors every fall go hundreds of thousands of American youth, those favored ones of earth from whose ranks come most of the trained men and women of our society. Yet tuberculosis has already laid its hand on many of these. During 1939-40, according to the report of the Tuberculosis Committee of the American Student Health Association, published in the *Journal Lancet*, 637 cases of tuberculosis were found in two hundred and forty-eight of these institutions with a total enrollment of 500,000 students, because it was looked for. Most of these infected students can be saved for useful, productive lives with a minimum of time lost.

What is the story where the college authorities report that no search is made? The fact that only 35 cases appeared in two hundred and twenty-seven institutions among 200,000 students during the same period provides the answer. But is that the whole story? No, for back of those 35 cases many more stand in shadowed ranks, already touched by the destroyer. It is easy to prove that tuberculosis is there—a tuberculin test, followed by an x-ray film of positive reactors, is the magic wand that will bring to light the hidden lesions. But when they are not found early we know the story too. Most of them progress to the stage where treatment is to be reckoned in years, and complete cure is the exception.

And what of the four hundred and two institutions whose administrators did not even reply to the questionnaire? One can only surmise that they, too, have failed to translate the thing they know into the thing they do. Some of them, perhaps, are even unaware that tuberculosis is now, as it has always been, a foe of youth.

Yet it is to the pursuit of knowledge that all these institutions are dedicated and it was many years ago that Ralph Waldo Emerson said: Education is not pouring knowledge into minds; it is not erudition. A person is not truly educated unless knowledge influences his

doing as well as his *thinking*. Insofar as learning alters and directs *behavior* it is education."

In this respect, unfortunately, educators follow but the common path. In the trade union, the insurance office and the department store, in the hospitals and the homes for the aged, wherever men and women are gathered together, tuberculosis may be found when looked for. No class is exempt; no land is free from it—it is an enemy power we know how to conquer, but the war is prolonged by "too little and too late."—Reprinted from *Tuberculosis Abstracts*, April, 1942.

## CORRESPONDENCE

### MILITARY MALPRACTICE INSURANCE

*To the Editor:* I wish to call to the attention of all physicians entering the armed services of the United States or serving as examining physicians for local selective-service boards that they may be sued by selectees, or by anyone in the armed services of the United States, treated by the medical officer, on an allegation of malpractice. This ruling, dated May 1, 1941, was made by the Judge Advocate General of the United States Army.

Military policies, available on and after April 10, 1942, provide \$2500 to \$7500 limits for \$10.00 a year. These policies are issued by the insurance companies solely for malpractice insurance covering physicians in military service. If any income is derived by the medical officer on active military service from association or agreement with a physician in private civilian practice, the military policy does not apply. If a medical officer desires a military policy, he must certify that he was a member of his state medical society or association when inducted into the service.

Medical officers discharged from the armed services and entering practice again should remember to reinstate their regular malpractice insurance policies for protection in civil life, if they desire such protection.

WILLIAM REID MORRISON, M.D.

520 Commonwealth Avenue  
Boston

## REPORTS OF MEETINGS

### NEW ENGLAND PATHOLOGICAL SOCIETY

A regular meeting of the New England Pathological Society was held on November 20, 1941, with Dr. B. Earle Clark presiding. Dr. William Dock, professor of pathology at Cornell Medical College, spoke on "The Kidneys and Hypertension."

Scarring or compression of the kidneys and partial occlusion of the renal artery or of the aorta proximal to the renal artery leads to sustained hypertension, and since this persists for hours after removal of the kidney it cannot be due to a reflex; it might be caused by decreased liberation of an antipressor substance or release of a pressor hormone, which seems likelier, since total nephrectomy does not cause a rise in pressure. All attempts to demonstrate a vasoconstrictor substance in renal hypertension have failed; indirect evidence from studies of flow in the limbs does not prove that such a substance is present in human patients and rules it out in the transient hypertension of acute glomerulonephritis (Pickering). Dr. Dock and his collaborators have found no difference in the pressure levels of control and renal hypertensive rats, rabbits and dogs, after destroying the central nervous system. Pithed animals are very sensitive to vasoconstrictor substances, including renin, and it is

therefore concluded that the renal pressor hormone acts by changing the set of the vasomotor center, and not directly on arterioles.

Perfusion of kidneys post mortem and x-ray films of the injected renal arterial bed prove that an organic increase in resistance to renal blood flow is not usual in hypertensive patients without uremia; narrowing of the main artery is even rarer. In most cases, the kidney shows, in addition to atheromatous narrowings, arteriolar change equal to that in the other kidney, whereas in Goldblatt-clamp hypertension, little or no change is present in the kidney protected by the clamp even though marked change occurs in the retinal vessels and in the opposite unprotected kidney. Accordingly, Dr. Dock considers most narrowed main renal arteries to represent late complications, not primary causes. There is strong evidence, based on the evolution of vascular disease in the eyegrounds and on studies of Goldblatt hypertension and pulmonary arterial sclerosis, that hypertension may cause or accelerate atherosclerosis and arteriolar degeneration. Therefore, it is most probable that renal sclerosis is a result, not a primary cause, of so-called "benign" hypertension. At present, it seems probable that inherent vasomotor instability or adrenocortical disease underlies many cases of arterial hypertension, and that the tendency to vascular degeneration inherited by some people leads to rapid renal, retinal, cerebral or coronary arterial disease if they become hypertensive. Others, especially women, have inherent soundness of the vascular tree, and after decades of hypertension show minimal damage.

Rodents, dogs, cats and men have easily recognized peculiarities of the first loop of the distal convoluted tubule (macula densa) and of the wall of the afferent arteriole. No definite change in this tissue is seen in most human hypertensive patients (benign, glomerulonephritic or pyelonephritic coarctation of aorta), or in rats, rabbits and dogs in which hypertension has developed slowly and gradually; changes have been seen by others in many types of renal hypertension in animals, and Dr. Dock has observed hyperplasia and swelling of the cells of the afferent arteriole in dogs with rapidly developing hypertension and has been much struck by the hypertrophy and fuchsinophilic granules in the arterioles of the hypertensive cat (Graef). He has also been struck by the severe damage to this tissue in amyloid disease, and suggests that the absence of hypertension in most amyloid uremic cases is due to the fact that the specific cells have been replaced by amyloid. However, it must be noted that uremia in amyloidosis often develops rapidly and may be due to an extremely severe damage to the adrenal cortex. Dr. Dock found excellent renal perfusibility in one case of amyloid disease with uremia. Careful study of amyloidosis, with and without hypertension and during life as well as post mortem, may prove valuable in correct judgment of the role of the juxtaglomerular tissue. The morphologist, whose observations usually start most clinical problems, may be able by refined technics in pedigreed cases to solve a complicated situation.

In the discussion, neither Dr. Soma Weiss nor Dr. Alan Moritz considered the evidence presented by the speaker sufficient to rule out the renal origin of hypertension. Dr. Weiss believed that the evidence drawn from the pithed-animal experiments was not foolproof, since it is known that vasoconstrictor substances may act differently under various conditions. Dr. Moritz stated that the possible causal relation of renal arteriolar disease and hypertension is still an open question.

# HARVARD MEDICAL SOCIETY

A regular meeting of the Harvard Medical Society was held at the Peter Bent Brigham Hospital on December 9, with Dr Soma Weiss presiding.

The case presentation was that of a forty-one year-old woman whose history dated from an attack of acute otitis media eleven months prior to admission. There were recurrent episodes of draining from the ears for three months followed by a period of one month without symptoms. Then began a train of manifestations including fever, chills and night sweats. Four blood cultures were found to be positive for *Streptococcus viridans*. Sulfadiazine therapy was instituted, and the patient also received several administrations of typhoid vaccine. This treatment was temporarily discontinued when she had what appeared to be a subarachnoid hemorrhage. During this therapy, there was great clinical improvement in November, however, her chills, fever and night sweats recurred and blood cultures were again positive. Sulfadiazine therapy was reinstituted, with clinical improvement again. One important point brought out in the discussion of this case was that crude liver extract or crude preparations of the vitamin B complex should not be administered when the sulfonamides are being employed, apparently the aminobenzoic acid responsible for the inactivation of these drugs is present only in the crude forms.

The speaker of the evening was Dr Henry A. Christian whose subject was "Glomerular Lesions of Subacute *Streptococcus Viridans* Endocarditis." This study was based on 11 patients at the Peter Bent Brigham Hospital with this disease. The gross descriptions were taken from the records, whereas the microscopic descriptions and conclusions are those of the speaker. It was interesting that in the gross these kidneys revealed the typical flea bitten appearance in only 13 per cent of cases. A moderate amount of edema and swelling was a common finding, on the other hand. Ninety per cent of the organs had infarcts microscopically, and 25 per cent of these were not noted grossly. It was concluded, therefore, that this already high percentage might have been even higher if better sections had been chosen. A correlation with the clinical record revealed that such infarcts are entirely unpredictable, for they seem, of themselves, to cause no urinary signs and symptoms.

Microscopically, the changes in the tubules are neither striking nor specific nor primary. The changes in the glomeruli, however, are multiple somewhat specific and important. In 80 per cent of the specimens, there was an intracapillary proliferation of cells, which were mostly endothelial but, to some extent, epithelial. This lesion, which is essentially the same as that of diffuse glomerulonephritis, appears to have little if any effect on the measurable kidney functions and causes no appreciable change in the urinary output or sediment. Some of these cells undergo varying degrees of degeneration, with a tendency to granulation of the cells and a decrease in size of the nucleus. Locally, epithelial crescents are found in 36 per cent, with fibrous degeneration of the cells in 26 per cent of specimens. The fibrous crescents may be detached from Bowman's capsule—an indication that degeneration occurs in the fibrous stage. Completely organized glomeruli are occasionally found, are variable in any given patient, and interestingly enough are not found in those with the worst kidney function. Embolic lesions are fairly frequent, but there are few in any given case. They are present in about 40 per cent of the kidneys but were numerous in only 4 cases. Masses of *Streptococcus viridans* organisms are present in approximately 6

per cent of cases. The most frequently encountered lesions macroscopically and microscopically are, respectively, infarcts (90 per cent) and a diffuse cellular proliferation similar to that of glomerular nephritis (85 per cent). Dr Christian believes that the hyaline changes are a manifestation of embolic thrombotic lesions, which are not found in normal glomeruli, contrary to the teaching of some.

Clinically, albuminuria appeared in about 75 per cent of cases, although the same degree of infarction was present in the remainder, hence, infarction cannot be the sole cause of this sign. Casts were found in surprisingly few urinary sediments and were usually of the simple variety. Hematuria was also present in 75 per cent of patients, but was rarely persistent. There were usually recurrent attacks of microscopic hematuria.

Correlation of the clinical and pathological findings reveals that infarcts are not a significant factor, and that embolic thrombotic lesions are not often associated with hematuria. Probably, the most constant association is with focal lesions, especially those of the epithelial crescent type. On the whole, the kidney function remains surprisingly good to the end. In no case in Dr Christian's series did death result from uremia. The phenol sulfonphthalein and urea-clearance tests were usually good, and it was found that infarcts might involve a large portion of the kidney without significantly impairing the function during the life of the patient.

The discussion was opened by Dr James P. O'Hare, who emphasized certain facts brought out by Dr Christian and raised the question of why there is no elevation of blood pressure in this condition, as in chronic glomerulonephritis. Dr Laurence B. Ellis of the Boston City Hospital, in corroborating the rarity of terminal renal manifestations, observed that he had seen only one such case in over five years of observation.

In closing the discussion, Dr Christian stated that the probable reason for the lack of hypertension is the absence of true vascular lesions. The lack of urinary symptoms is probably due to the short course of the disease. Nevertheless, lesions have been found in experimental poisoning with uranium so that they may be considered nonspecific glomerular lesions. And since the lesions found in glomerulonephritis are the same as those caused by the *Streptococcus viridans*, it is possible that the lesions of the former condition are the result of the streptococcus itself rather than an effect of allergy, which is the most widely accepted current belief.

## BOOK REVIEWS

*Malignant Disease and Its Treatment by Radium*. By Strinford Cade, F.R.C.S. 4°, cloth, 1280 pp., with 623 illustrations, many in color. Baltimore: William and Wilkins Company, 1940. \$18.00.

This elaborate study, which gives a comprehensive picture of treatment by radium of cancer, is praiseworthy but outmoded. The swift progress in roentgen ray therapy has so altered the field that as one leafs through these pages one is reminded of the brave but tactically outmoded struggles of the British and French armies against the Panzer divisions. The photographs of wooden helmets for the application of radium to an intracranial tumor, for example, have more value as a medical curiosity than as an aid to the tumor therapist.

The section on the physical aspects of radium is adequate, and the section on the biologic effects of radiation is interesting although somewhat sketchy. The illustra-

tions are clear and well chosen. Some of them are in color.

For the experienced practitioner who has a wide knowledge of the uses and limitations of radium and x-ray therapy in the field of cancer, the book will be of value. For others, although well and honestly written, it cannot but be misleading.

*Bibliographia Primatologica: A classified bibliography of primates other than man. Part I. Anatomy, embryology and quantitative morphology; physiology, pharmacology and psychobiology; primate phylogeny and miscellanea.* By Theodore C. Ruch, B.Sc., Ph.D. With an introduction by John F. Fulton, M.D., Ph.D. 4°, cloth, 241 pp. Springfield, Illinois: Charles C Thomas, 1941. \$8.50.

The use of primates as experimental animals, particularly in the study of the intricacies of the brain, in recent years has resulted in many studies on the animals themselves. Laboratories of primate biology have come into being, bringing new knowledge of the habitats, conditions favorable to transportation, details of sexual life and conditions of breeding. Some types, of great research value, are now being bred for the first time in this country.

With this impetus to study of the primates, the literature, scattered widely in many journals, needed correlation and classification. This Dr. Ruch has done, with bibliographic accuracy, for nearly four thousand separate articles. To the usual reference material are added many facts in abbreviated form: the proportion of the paper given to primate material when other topics are considered; notes on plates, figures, tables and references; and the genera of the animals studied.

This painstaking and finely done piece of bibliographic research is the first book issued under the auspices of the Historical Library of the Yale Medical Library. It augurs well for future publications from this source.

*Leaders of Medicine: Biographical sketches of outstanding American and European physicians.* By Solomon R. Kagan, M.D. 8°, cloth, 176 pp., with 4 illustrations. Boston, Massachusetts: The Medico-Historical Press, 1941. \$3.00.

This volume is in the familiar pattern of Dr. James J. Walsh's *Makers of Modern Medicine*. It consists of a dozen brief biographic sketches of outstanding American and European physicians of the nineteenth century, from Jacob Henle to William Henry Welch. There are engraved portraits of both these men, and of Paul Ehrlich and Jacob Solis-Cohen.

All the biographies are extremely vivid and well documented. The best is that of Sir William Osler, perhaps because he was intrinsically the greatest of the group. Others of almost equal interest, however, are those of Virchow, Mitchell, Jacobi, Allbutt, Billings, Cohnheim and Weigert.

A great debt of gratitude and appreciation is owed to Dr. Kagan as a continuator of the work of Walsh and of Garrison as American medical historians.

*Essentials of Electrocardiography: For the student and practitioner of medicine.* By Richard Ashman, Ph.D., and Edgar Hull, M.D. Second edition. 8°, cloth, 373 pp., with 122 illustrations and 5 tables. New York: The Macmillan Company, 1941. \$5.00.

The second edition of this valuable text will be greeted with interest by all who are familiar with the first. They will find practically a new book incorporating a great deal of material regarding the basic theory of the electrocardio-

gram that has come to light within the last five years. They will also find a much more adequate treatment of the subject of chest leads than was possible in the first edition.

Unlike many textbooks, this volume is stimulating reading because it bears the stamp of originality all the way through and is not merely a summary of the work of others. Although some students of the subject will find points of disagreement, the general presentation leaves little to be desired. To this reviewer, however, it appears that the authors have, on the basis of theory, carried their refinement of electrocardiographic diagnosis a little farther than existing post-mortem correlations warrant. Specifically, one could wish for a more substantial basis than the authors present for interpretation of deviation of the axis of the T waves in clinical terms. Because of the already prevailing tendency of physicians to read too much into the electrocardiogram, this book is to be recommended more to cardiologists of experience than to beginners.

*Essentials of Dermatology.* By Norman Tobias, MD 12°, cloth, 497 pp., with 143 illustrations. Philadelphia: J. B. Lippincott Company, 1941. \$4.75.

The reviewer was amazed at the dermatology contained in this small book, free from the usual verbiage of most textbooks on dermatology. The clinical descriptions are concise, the histopathology contains the necessary details, and the treatment is practical. The classification of the diseases is not confusing, owing to the repetition of entities overlapping in the various sections, when the disease cannot be classified in any one group. The book reflects the author's comprehensive knowledge of the literature, for otherwise he would not have been able to infer essential principles of past and present dermatology. It is noticeable that the little volume includes the most recent studies in dermatology.

The author deals with the treatment of cutaneous diseases in a most practical manner. The prescriptions suggested are not of the shotgun variety, but are sensible in their simplicity, with explanations of the reasons for their use.

The book is legibly printed on good paper, compact and well illustrated. Many of the pictures are excellent; however, at least a third of them, because of poor photography, could be removed without loss. This book is so easily read that it would be no task to the student, and therefore can be recommended to him. It would be very useful to general practitioners and even to dermatologists who desire a quick review of the essentials in their specialty.

*Microbes Which Help or Destroy Us.* By Paul W. Allen, Ph.D., D. Frank Holman, Ph.D., and Louise Allen McBe, M.S. 8°, cloth, 540 pp., with 102 illustrations and 14 color plates. St. Louis: The C. V. Mosby Company, 1941. \$3.50.

This semipopular account of bacteriology covers the entire field, with emphasis on history, public health and the prevention of disease. The story has been told in better form many times before, and it is difficult for the reviewer to see why this book was published. Many of the illustrations are poor and crude. The facts in general are correct, and the book may be safely put in the hands of the public. As a text of particular value, however, it cannot be highly recommended.

## A STATISTICAL STUDY OF SIX HUNDRED AND SEVENTY-ONE CASES OF APPENDICEAL PERITONITIS\*

HORATIO ROGERS, MD,† AND HENRY H FAXON, MD‡

BOSTON

### INTRODUCTION

OF all the surgical diseases that engage wide spread interest, appendicitis is undoubtedly the most familiar. It is not surprising therefore that the literature should be so voluminous or that it should cover so many different and almost unrelated aspects.

The present study is confined to the clinical problem of peritonitis in patients brought to the hospital for appendicitis. Between 1929 and 1940, the staff of the Massachusetts General Hospital treated 5055 cases of appendicitis, with a mortality

will often be difficult and their mortality discouragingly high. The present study concerns these cases.

The surgeon's hand has been greatly strengthened by the recent progress in chemotherapy, surgical bacteriology, blood chemistry and intestinal intubation, and it is clear that the mortality rate of appendiceal peritonitis is being reduced by their practical application. Our own, for example, has dropped from 25 per cent in 1929 to 6 per cent in 1939, and similar reductions are being widely reported. However, they are only aids and cannot be substituted for clinical judgment and surgical skill. We have therefore concentrated this study on the clinical factors that can be shown to affect the mortality rate of appendiceal peritonitis.

Peritonitis, within the meaning of this study, consists in the presence of gross perforation, pus in the peritoneal cavity or abscess formation as seen at operation or autopsy or as made clear by the clinical course of the disease. Cases wrongly diagnosed have been excluded. Although the absence of gross peritonitis could easily be recognized at operation, we have found it impossible to determine the exact extent without doing a dangerous and unjustifiable amount of exploration. This experience, in addition to the fact that treatment must actually be planned entirely on the basis of the clinical data available before operation, has persuaded us to abandon the purely pathological classifications so often seen in the literature in favor of a classification based on preoperative clinical findings. Of these, we have taken mass formation to be the most fundamental. The presence of a palpable mass gives indisputable evidence of some degree of localization and hence, at least from the point of view of treatment, serves to separate the group in which localization has already occurred from the group in which localiza-

TABLE 1 Incidence and Mortality of All Cases of Appendicitis

rate of 2.04 per cent, but the mortality rate for the 384 patients without peritonitis was 0.37 per cent, contrasted with one of 12.97 per cent for the 71 patients who did have peritonitis (Table 1). Efforts have been and must still be directed toward the earlier diagnosis and treatment of appendicitis, so that this excessive mortality may be avoided, but at the same time one must recognize the facts that there will always be cases of appendiceal peritonitis, and that their management

tion has not and perhaps will not take place. Because these two groups are readily distinguishable clinically and because the treatment differs basically in each, they are classified and reported separately as Parts I and II of this study.

The objection may be raised that such a classification fails to permit any satisfactory comparisons between our figures and those from other clinics where the figures are based on a strictly pathological classification of cases. Our attempts to derive really comparable mortality figures from various published reports have convinced us of the practical impossibility of taking all the relevant factors into account or even of knowing, in any given report, what they were. The essential factors governing the mortality rate of appendiceal peritonitis in any clinic are the type of cases received, the accuracy of clinical appraisal, the policy of treatment and the technical quality of the treatment. If any of these essential factors are ignored, the

comparison must be fallacious and misleading. We are therefore less concerned with comparing our mortality statistics with those of others than with trying to find out what factors influenced them and how they may be improved.

During the three years occupied in personally analyzing the records of cases of appendiceal peritonitis admitted to the Massachusetts General Hospital between January 1, 1929, and January 1, 1940, we have also treated or supervised the treatment of all cases of so-called "ruptured appendix." The clinical phase of the study was of value not only in enabling us to investigate new technics but also in forcing us to be realistic in our analysis of the previous records. These records relate to house patients, some of whom were operated on by members of the visiting staff and some by the house staff. The records were uniformly good, although not every one contained all the items of information we sought.

PART I. FOUR HUNDRED AND FORTY-FOUR CASES OF APPENDICEAL PERITONITIS WITHOUT PALPABLE MASS

The patients served by the Massachusetts General Hospital are almost entirely white and mainly comprise city dwellers. Sixty-five per cent of the present group were males. The mortality rate among males was 14.2 per cent, in contrast with 19 per cent among females, perhaps because the presence of peritonitis offered a more difficult differential diagnosis in females and thus led to a relatively higher mortality. The age incidence and mortality by decades (Table 2) of these cases were very similar to those for appendicitis as a whole: the mortality was lowest among young adults, in whom the incidence was highest, and highest among patients at the extremes of life, in whom appendicitis is least common. It is noteworthy, however, that 18 per cent of the 444 patients were infants and children under ten years of age;

ment. Inherent diagnostic difficulties and the pernicious habit of administering cathartics to fretful children are undoubtedly responsible.

During this eleven-year period, there have necessarily been variations in the technical quality of

this suggests that an unfortunately large number of young children with appendicitis are being allowed to progress to the stage of actual peritonitis before being taken to the hospital for treat-

the treatment and the accuracy of clinical appraisal, as well as in the annual difference in the number and type of cases and progressive changes in the policy of management. No one of these factors alone was responsible for the different annual mortality rates (Table 3), although the types of cases appear to have made the greatest difference, and ironically enough, of all the possible variables this is the one over which we exercise the least control.

since it depends almost entirely on the diagnostic acumen of the medical attendant. That the policy of treatment was rather inflexible during this period is suggested by the consistently high proportion of patients subjected to immediate appendectomy—100 per cent in the highest year and 74 per cent in the lowest, with an average of 89 per cent. In the future, an increasingly flexible policy will be adopted, since it is shown that newer methods not only make appendectomy itself safer but also guarantee the surgeon greater freedom to choose the optimum time for doing it. But this widening scope of free choice, to be successful, implies the exercise of a high degree of clinical judgment and points directly to the importance of an accurate evaluation of preoperative clinical factors in terms of prognosis.

### PROGNOSTIC SIGNIFICANCE OF HISTORY

#### *Episode Suggestive of Acute Perforation*

At some definite time in their illness, one quarter of the 444 patients described a sudden episode that suggested acute perforation of the appendix, and the mortality (25 per cent) among these 115 patients was almost double that (13 per cent) of

ill give a history suggestive of acute perforation of more than six hours' duration, the symptom probably has no prognostic significance.

In the very ill group, the delay of even six hours (Table 4) between the acute perforation episode and operation resulted in a mortality rate (50 per cent) five times as great as that resulting from operation within six hours. This mortality rate certainly challenges the wisdom of routine appendectomy under such circumstances. On the other hand, we are not prepared to say that conservative treatment would have resulted better, since this group probably contains most of the cases in which spontaneous localization will never occur. We have not yet had enough experience with appendectomy combined with local chemotherapy to know how effective it will prove in this situation. We do know that in this group every case must be studied individually, and that operation should be elected only after all the significant factors have been weighed. Even then, a predetermined type of appendectomy should be avoided, and full advantage should be taken of whatever additional information is furnished by operative visualization to select the safest further procedure under the circumstances.

#### *Duration of Illness Before Operation*

The familiar phrase, "Too late for an early operation, and too early for a late operation," reflects the value that has always been attached to the time element as a guide for safe operation. In this series, the mortality rate more than doubled after the first day of the disease (Table 5) and did

TABLE 4 *Prognostic Significance of Time of Operation in Ill and Not Very Ill Patients with Acute Perforation*

the 329 patients whose story suggested no definite hour of perforation.

Actually, the prognostic significance of such a story was confined to those patients who looked very ill on admission (Table 4). The mortality rate (42 per cent) was six times higher than that (7 per cent) of the patients who, with or without a history of acute perforation, did not look very ill. The story, the appearance of extreme illness and the high mortality were all presumably due to a relatively sudden gross contamination of the unprotected peritoneal cavity, either from an abrupt purging of protective adhesions or from a massive rupture of an insufficiently walled-off appendix. The patients who did not look very ill presumably did not have this pathologic picture, since so few (7 per cent) of them died. It must therefore be assumed that when patients who do not look very

TABLE 5 *Mortality and Morbidity According to Day of Disease on Which Appendectomy Was Done*

not decline until after the fifth day. It is of interest that the postoperative course of the survivors was little influenced by the day of operation, however, even when it fell within the most dangerous period, and this suggests that the day of the disease had much more significance for some patients than for others. The time element therefore served only to point out a group containing patients who would fail to survive appendectomy; it did not

identify the patients. This ultimate desideratum must depend on an appraisal of all the other significant factors in each case.

Chills

The preoperative occurrence of chills was described in the history of 41 patients, representing a minimal incidence of 9 per cent. These patients suffered a mortality rate of 22 per cent, as compared with a mortality of 16 per cent for the whole group of 444. The proportion of stormy convalescences and the average hospital stay of the 32 survivors did not differ from the average for the whole group. There were 4 recognized cases of pylephlebitis, 3 of which were fatal.

This experience may be summarized by the statement that about one tenth of the patients with appendiceal peritonitis without a palpable

nificant relation to the mortality rate than any other single preoperative factor. Reducing the classification to "very ill" and "not very ill," we have found the mortality associated with the former group (33.8 per cent) to have been almost five times higher than that associated with the latter (7.4 per cent), regardless of whether or not immediate appendectomy was carried out (Table 6).

Absent Peristalsis

Definite, complete absence of audible peristalsis in 53 cases was associated with a mortality rate (28 per cent) four times higher than that (7 per cent) of 115 cases in which the peristalsis was definitely present, and almost twice as high as the 16 per cent rate for 25 cases in which the presence of peristalsis was doubtful. As a single measure of

TABLE 6. Mortality in Cases, Variouslly Treated, According to Degree of Illness on Admission.

Averages				33.8			7.4

mass gave a story of chills, that nine times out of ten it had no prognostic significance, but that the tenth time it meant a probably fatal pylephlebitis.

Previous Attacks

The well-recognized tendency of repeated attacks of appendicitis to increase in severity suggests that peritonitis following a series of attacks should result in a higher mortality than peritonitis complicating an initial attack. It is therefore of some interest that the mortality was about 2 per cent lower in a group of 110 patients who had had repeated attacks than in a similar group who developed peritonitis in their first attack. The difference, though small, suggests that the rapidity and extent of spread of peritonitis may be limited or delayed by the effects of the inflammatory reactions due to previous attacks.

PROGNOSTIC SIGNIFICANCE OF PHYSICAL EXAMINATION

Degree of Illness

The item "general appearance," which appears on the examination sheet in use at the Massachusetts General Hospital, is filled in by the admitting surgeon with a remark — such as "moribund," "very ill," "moderately ill" or "not ill" — that expresses his first impression of the patient's condition. This item has proved to have a more sig-

lethal degrees of peritonitis, it appeared to rank next in importance to the general appearance of the patient.

Abdominal Spasm

In 215 cases, spasm was described as diffuse or generalized, and the mortality was 21 per cent. This was twice as high as the 10 per cent mortality suffered by 199 patients with only local spasm, and over three times higher than that (6 per cent) of 16 patients who had no abdominal spasm at all. Thus, on the basis of 430 cases, the extent of spasm appeared to be the third most significant factor in the physical examinations.

Rectal Tenderness

Almost twice as many (21 per cent) of the 77 patients who did not have rectal tenderness died of the 277 patients who did (13 per cent). The rather surprising relation suggests that the direction in which the peritonitis spreads is perhaps of more significance than its actual extent, and such an explanation fits in with the well-recognized ability of the pelvic peritoneum to resist infection.

PROGNOSTIC SIGNIFICANCE OF LABORATORY DATA

Leukocyte-Pulse Index

That the original temperature, pulse and leukocyte count have more than a diagnostic significance

is generally appreciated, but just how and to what extent they may be used as an aid to prognosis and treatment is less well understood.

There is ample reason to believe that an abnormally rapid pulse in a patient with peritonitis is a measure of toxicity, whereas an accompanying leukocytosis reflects the degree to which the patient can mobilize his cellular elements to resist infection. (The significance of temperature variations is less clear, but it appears roughly to parallel that of the leukocyte count.) The relation between the amount of leukocytosis and the rapidity of the pulse might therefore be expected to represent the relative strength of the forces of destruction and of protection and hence to have a direct bearing on the prognosis of the case. In the absence of acute sepsis, such a concept would, of course, have no meaning.

We have attempted to express this relation by dividing the thousands of the leukocyte count into the pulse rate, to obtain a single number, which may be called the "leukocyte-pulse index." It might have been possible, by mathematical manipulations, to cancel the normal element from both components and thus obtain a truer expression of

succumbed; the leukocyte-pulse index averaged below 6 for the survivors and above 6 for the fatalities, and children had the same relation as adults but based on higher counts. From these averages, we have taken 6 to represent the critical point in mortality prognosis.

The mortality for patients with a leukocyte-pulse index below 6 was 6 per cent, but for those having an index above 6 it was 21 per cent, or more than three times as great (Table 7). This difference is large enough to exclude coincidence, so that a definite prognostic significance may be attached to it in cases of acute appendiceal peritonitis without mass formation.

#### Other Laboratory Data

Routine urine examinations were done, but we have not included them except to note how often blood cells appeared in the sediment as a possibly confusing diagnostic factor. Red cells were found in 19 cases and white cells in 70. We examined catheter specimens of female patients to be certain that the cells originated in the urinary tract.

Differential blood counts and other special procedures were omitted from this study, since there were too few for useful analysis. We believe that they should be done whenever the clinical diagnosis is in doubt.

TABLE 7. *Relative Prognostic Value of Various Clinical Factors as Determined by the Mortality Rate Associated with Each Factor, Based on 444 Cases with a Total Mortality of 15.9 Per Cent*

CLINICAL FACTOR	MORTALITY WITH FACTOR PRESENT	MORTALITY WITH FACTOR ABSENT
	%	%
Story of "acute perforation" in very ill patient	42	7
Patient very ill on admission	34	7
Peristalsis definitely absent	38	9
Wrong preoperative diagnosis	33	15
Age over sixty years	32	15

Leukocyte pulse index above 6	21	6
Story of "acute perforation"	25	13
Abdominal spasm diffuse	21	10
Operation not on first day of disease	18	7
Age below ten or above sixty years	24	13
Abdominal spasm present	16	6
Rectal tenderness absent	21	13
Story of preoperative chills	22	15
Age under ten years	20	15
Female sex	19	14
First attack of appendicitis	13	11

#### PROGNOSTIC SIGNIFICANCE OF DIAGNOSTIC ERRORS

As mentioned above, we have eliminated those cases in which the diagnosis of appendiceal peritonitis was proved to be wrong. Most of them were uncomplicated acute appendicitis without gross peritonitis and were treated by immediate appendectomy, and the patients did well, as would be expected in the early stages of the disease. So far as we could tell, no patient was allowed to rupture his appendix in the hospital because of the mistaken idea that it had already ruptured and should therefore be treated conservatively. The danger of falling into this error must be recalled, however, when the choice of deferring operation is under consideration.

The only diagnostic errors included in this study occurred in the cases that were actually appendiceal peritonitis but were mistaken for something else. There were 18, of which 6 were fatal, a mortality of 33 per cent, which is more than double that for the 426 correctly diagnosed cases. The mistaken preoperative diagnoses were perforated peptic ulcer in 5 cases (2 fatal), diagnosis in doubt in 4 cases (2 fatal), acute salpingitis in 3 cases (1 fatal), acute unruptured appendicitis in 2 cases, acute hepatitis in 1 fatal case, and acute cholecystitis, acute pancreatitis and ovarian carcinoma each in 1 case.

the significant relation, but we have refrained in the interests of simplicity. For example, with a leukocyte count of 20,000 and a pulse rate of 100, the index is 100 divided by 20, or 5.

In tabulating the average figures for living and dead patients, we have used the preoperative data of 335 patients subjected to immediate appendectomy, omitting the 27 patients over sixty years of age because they showed a rather different relation and yet were too few to permit an adequate investigation of this variation. The 292 patients who survived tended to have more leukocytosis in relation to their pulse-rate than the 43 who

It is apparent that these errors affected the mortality prognosis unfavorably only so far as the misdirected treatment of each patient was incompatible with recovery from acute appendiceal peritonitis.

#### SUMMARY OF PROGNOSTIC PREOPERATIVE FACTORS

Table 7 presents some of the factors that are familiarly thought of in terms of pathology but could be more directly used as guides for the selection of treatment if they were interpreted in terms of prognosis. An attempt has been made to arrange them in the order of their prognostic significance, the mortality rate of two groups of similarly treated patients being contrasted; one

moribund (Table 6) — reflects the nature of the policy then in force, and the mortality of 14 per cent seems remarkably low in view of the fact that one third of the patients were very ill at the time of operation. By contrast, the small group selected for expectant treatment was largely (two thirds) composed of very ill or moribund patients, and that this group should have suffered a 39 per cent mortality rate is not surprising.

Evidence of a gradual change of policy may be found in the annual figures (Table 3). The proportion of patients subjected to immediate appendectomy in the presence of peritonitis declined from 100 per cent in 1929 to 87 per cent in 1939, with a parallel decline in the mortality rate from

TABLE 8. *Mortality According to Choice of Treatment.*

TREATMENT	NO. OF CASES	INCIDENCE %	NO. OF DEATHS	MORTALITY %
Immediate operation	408	92	57	14
Immediate appendectomy	395	89.1	50	12.6

Deferred appendectomy	9	2.0	0	0
No operation	11	2.6	8	73
Totals	444		71	
Average				15.9

group was characterized by the presence of some factor, and the other group by its absence. It is realized that no such correlation can be taken too literally because the contrasted groups could not be identical in every particular save the one under consideration.

We believe that when several of the most unfavorable factors are combined in one case, the patient must be recognized as an extremely bad risk, and that particular care must be taken in selecting the safest treatment.

#### INFLUENCE OF TREATMENT ON MORTALITY RATE

##### *Choice of Treatment*

At the Massachusetts General Hospital during most of the period covered by this study, the policy favored immediate operation at any stage of the disease, provided only that the patient appeared strong enough to stand the operation. More recently, the wisdom of operation in the presence of gross peritonitis has been increasingly questioned, particularly since the newer methods of controlling ileus, distention, fluid imbalance and infection have increased the efficacy of expectant treatment.

The fact that immediate operation was chosen in 91.9 per cent of our cases (Table 8) — even for 84 per cent of the patients who were very ill or

25 to 6 per cent. We believe that this shift in policy and improvement in the mortality figure was partly due to an increasing recognition of the value of accurate individualization.

##### *Technical Factors*

It is apparent that the different degrees of technical skill of the surgeons who operated on the patients in this series must have had a significant effect on the mortality rate, but one that would be extremely difficult to calculate or to control. It has been profitable to examine certain technical factors, however.

*Type of incision.* For purposes of comparison we have divided incisions into two main types: lateral and medial. The former refers to the relatively small gridiron incisions, as described by McBurney and Rockey, characterized by a minimal exposure of small bowel. The medial type includes midline, paramedian, rectus-splitting and rectus-retracting incisions, all characterized by greater exposure and manipulation of viscera, especially small bowel.

Appendectomy was seldom done through a McBurney type incision, and its use in case without a mass appears to have made no difference in the mortality rate. The survivor of appendectomy had an identical incidence of stormy convalescence (36 per cent) and average

an identical number of hospital days (twenty), regardless of the type of incision used.

The choice of incision appeared to make a great difference in the 26 cases of incision and drainage without appendectomy: the mortality was almost three times higher when a median type of incision was used (Table 9). Again, the survivors had an identical incidence of stormy convalescence (40 per cent), regardless of the type of incision, which is perhaps only another way of saying that the patients did or did not get fatal general peritonitis as a result of surgical manipulations.

We believe that trauma to peritoneal surfaces with gauze packs, breaking down of protective adhesions and contamination of uninfected areas

of the others depended largely on the current popularity of one or another type.

Obviously, the correct choice of the anesthetic for every case is important, and if in every case the technic of its administration could be perfect, the correct choice would be solely a matter of correctly evaluating each patient. But faulty technic, resulting in an adequate degree of relaxation for the gentle, careful, safe sort of surgery that is essential in appendiceal peritonitis, may make any choice wrong. The correct choice must therefore depend partly on the quality of the available anesthesiologist, partly on the nature of the proposed operation, partly on the technical capabilities of the surgeon, and partly on the patient's physical and

TABLE 9. *Type of Incision and Associated Mortality.*

OPERATION	MEDIAL TYPE INCISION			LATERAL TYPE INCISION		
	NO OF CASES	NO OF DEATHS	MORTALITY %	NO OF CASES	NO OF DEATHS	MORTALITY %
Appendectomy, immediate	360	45	13	32	4	13
Appendectomy, deferred	5	0	0	3	0	0
Incision and drainage alone	17	10	59	9	2	22

Averages			14.4			13.6

increase the mortality rate regardless of the incision through which such offenses are committed. They were absolutely inexcusable in the performance of simple drainage, in which adequate exposure was not a consideration. In appendectomy, on the other hand, the demands of adequate exposure and avoidance of fatal trauma had to be reconciled, and the care and skill of the surgeon were apparently of greater consequence than the type of incision.

The medial type of incision is frequently advocated for females for convenience in reaching the pelvic organs, should they prove to be the true source of the symptoms. There is no objection to this in the absence of peritonitis, but it may result badly when gross appendiceal peritonitis is present. When the presence of peritonitis is in doubt, two incisions are safer than one disastrously wrong one.

*Anesthetic.* No deaths could be definitely attributed to the anesthetic, but poor choice and poor administration undoubtedly contributed to some of them. Ether (287 cases), spinal (115 cases) and local (28 cases) anesthetics were most frequently chosen. How much the mortality associated with each type relates to the anesthetic and how much it reflects the sort of cases in which each was used cannot be determined. The specific reasons for choosing a spinal anesthetic in 23 cases and a local in 28 cases were recorded, but the choice in most

mental condition. We are convinced that these considerations fundamentally influence the mortality rate, but unfortunately they cannot be expressed in terms of statistics.

*Length of operation.* The time from the skin incision to the application of the dressing was accurately recorded in 392 appendectomies. The 392 operations averaged forty-nine minutes and resulted in a mortality of 12.6 per cent.

As might be expected, the mortality was higher among very ill patients (26 per cent), even though their operations averaged only about five sixths as long as those of not very ill patients. Comparing the average length of operations that resulted in death and in recovery, it was seen that among good-risk patients long operations were associated with death and shorter operations with recovery, whereas among very ill patients the shorter operations were followed by death and the longer ones by recovery. It is thus clear that there is no simple relation between length of operation and mortality. A comparison of the actual mortality rates for each length of operation shows that the shortest operations did not have the lowest mortality rates among either the very ill or the not very ill patients. In both groups, the lowest mortality was for operations lasting between fifty and sixty minutes, and after one hour the mortality rate began to rise (Table 10).

We may safely assume that what determined

the length of these operations was how difficult the removal of each particular appendix proved for the particular surgeon, in addition, of course, to his own estimate of the need for haste. When the combination resulted in a degree of damage from which recovery was impossible, the patient died. Viewed in this light, our figures mean that speed is not in itself desirable, that avoidance of trauma is essential, and that if an appendix cannot be removed without undue trauma in one hour it should not be removed by that surgeon at that operation.

The length of 83 appendectomies in children under eleven was thirty-six minutes, and the mortality was 15 per cent. Possibly, safe appendectomy

out through a stab wound rather than through the main incision. Intestinal obstruction developed in only 8 (2 per cent) of the 415 drained cases, and was fatal in only 1 case (0.2 per cent).

In 18 cases, the abdomen was closed without drainage. Two of these patients were very ill, and 16 were not very ill, at the time of operation. All 18 recovered. One developed intestinal obstruction, which required operation on the seventh day after appendectomy. Three others developed residual abscess requiring drainage. Five had stormy, prolonged convalescence, and the remaining 9 did well.

On the basis of this experience, we must conclude that properly placed cigarette drains do little c

TABLE 10. Mortality Rate for Each Length of Operation According to Degree of Illness in Cases of Immediate Appendectomy.

LENGTH OF OPERATION <i>min</i>	VERY ILL PATIENTS			NOT VERY ILL PATIENTS			ALL PATIENTS		
	NO OF CASES	NO OF DEATHS	MOR- TALITY %	NO OF CASES	NO OF DEATHS	MOR- TALITY %	NO OF CASES	NO OF DEATHS	MOR- TALITY %

can be done more rapidly in children than in adults, but in the presence of peritonitis children tolerated rapid (and therefore perhaps rough) appendectomies no better than adults.

*Use of drains.* The time has passed when the surgeon at operation can fall back on some simple rule of thumb such as "When in doubt, drain" or "When in doubt, do not drain" and be satisfied that he has done the best thing for the patient. In view of the controversial opinions in the literature on the theoretical value of drainage, he cannot be blamed if he finds himself in doubt most of the time. With so many conflicting views advanced, there may be some practical value in noting the actual effects that could be attributed to the use of drains in the present cases.

Drains were used in the vast majority (96 per cent) of the 433 operative cases. Pus was removed by the suction tip, and two drains were placed most frequently (258 cases), one in the pelvis and one lateral to the cecum. Less frequently (128 cases), only one drain was used, either lateral to the cecum or in the pelvis. Three drains were used in 20 cases, and four drains in 9 cases.

An attempt was always made to avoid having any drain in contact with the small intestine or appendix stump. For this reason, it was thought desirable in 55 cases to bring the drain or drains

no harm, and that we have no evidence that would justify omitting them in cases of gross appendiceal peritonitis merely as a matter of policy.

*Other factors.* In recent years, blood transfusions have been given with greater frequency. In all, 51 of the 444 patients were transfused, each of these patients averaging two transfusions. Twenty-two patients died, and 29 recovered. These were obviously the sickest patients.

Chemotherapy was used successfully in 4 of the more recent cases covered by this report. Although it is now being used with increasing frequency, we have not had sufficient cases for useful analysis.

Smears and cultures may also assume greater importance as aids to treatment and prognosis, but since their full value was not appreciated during the earlier years covered by this study and since the laboratory methods have been changing and improving, we are not in a position to include this very interesting aspect of treatment.

There can be no question that part of the recent improvement shown by our own mortality figures and by those of others is due to improved methods of postoperative care based on more efficient therapeutic apparatus and better understanding of applied biologic chemistry. These factors, however, do not lend themselves to the statistical method of analysis, and we have therefore not attempted to

evaluate them as we have certain other technical factors concerned with the mortality rate.

### COMPLICATIONS

Residual abscesses following appendectomy (5 undrained, 35 drained) were encountered in 40 cases, with 4 deaths and an average of thirty-three hospital days for the survivors. Spontaneous resolution of the abscess took place in 20 cases. In the other 20, abdominal incision and drainage was necessary in 16, rectal puncture in 4. Nonfatal pneumonia was seen in 4 cases, and pneumonia was present in 8 cases of fatal peritonitis. Pulmonary infarcts were recognized in 2 cases, the patients averaging twenty-seven hospital days. Pulmonary collapse in 10 cases did not increase the length of hospitalization. There seemed to be no correlation between these pulmonary complications and the type of anesthesia.

There were 24 cases of major wound sepsis, 1 of wound dehiscence, and 1 of hemorrhage from the wound, all in drained cases, resulting in an average hospital stay of twenty-six days. Fecal fistula developed in 3 cases, with an average hospitalization of forty-four days, and all closed spontaneously. Two incisional hernias were noted, both following drained rectus-retracting incisions.

Nine cases of intestinal obstruction developed; 1 was fatal, and the other 8 resulted in an average hospital stay of thirty-eight days. Six of these patients had ileostomy done to relieve serious obstruction, since the Miller-Abbott tube was not then available.

Phlebitis lengthened the hospital time to twenty-seven days in 2 cases.

There was 1 case each of nonfatal pylephlebitis, urinary fistula, empyema, herpes zoster and pulmonary embolism, the hospital stays varying from one hundred and seventeen to seventeen days but averaging well above the nineteen-day period that was the average for the whole group.

### CAUSES OF DEATH

Of the 71 deaths, 49, or almost 70 per cent, were caused by general peritonitis, with or without such concomitant complications as pneumonia in 8 cases, intestinal obstruction in 3, septicemia in 1 and massive wound sepsis in 1. Six deaths were caused by pneumonia, with concomitant diabetes in 1 case and wound sepsis in 1. Three were caused by pylephlebitis, and 3 by pulmonary embolism. Sepsis, subphrenic abscess, gas gangrene, uremia, acute nephritis, right heart dilatation, myocardial failure and acute respiratory failure each caused death in 1 case; there were 2 undetermined causes, 1 of sudden death on the operating table and 1 of epileptiform convulsions six hours after operation, no autopsy being performed.

### PREVENTABILITY OF DEATHS

We have studied the records of the fatal cases to see if any of the 71 patients could have been saved by different management in the hospital. This is not easy to ascertain, since a number of elements, some of them unknown and indeterminate, combined to produce each death. We have, however, tried to pick out the cases in which some error that is known to be frequently fatal may have been made.

### Errors in Diagnosis

Two patients were explored through an upper abdominal incision for perforated duodenal ulcer a few hours after onset of symptoms, and both died of general peritonitis caused presumably by manual dissemination of pus from a ruptured appendix. This disaster would have been averted if the appendix had first been explored through a small incision in the right lower quadrant.

A nineteen-year-old girl at autopsy showed co-existent chronic salpingitis and ruptured appendix, with general peritonitis. She had entered the hospital on the first day of her acute symptoms, and had been treated conservatively for pelvic inflammation.

One woman entered the hospital in premature labor with atypical pain, died without operation, and at autopsy showed a ruptured appendix, with general peritonitis.

A child was studied for eleven days on our children's medical service, died without a diagnosis, and was found at autopsy to have a ruptured appendix and general peritonitis.

These were undoubtedly all difficult diagnostic problems, and similar ones are constantly being seen. Since appendicitis is by far the commonest abdominal emergency, we believe gentle exploration through a small McBurney incision to be justifiable whenever the presence of a ruptured appendix cannot be excluded and the contemplated treatment is incompatible with recovery from appendiceal peritonitis. We have frequently attempted to aspirate the peritoneal cavity in doubtful cases, with no ill effects so far, but a negative result is of no diagnostic significance, and the procedure cannot be regarded as free of risk.

### Wrong Choice of Treatment

Eleven of the appendectomies that were done between the third and the seventh day of the disease were fatal, the patients dying of general peritonitis. We cannot say that this was a wrong choice of treatment in these particular cases, but we can point out again that this is the phase of the disease in which appendectomy carries the highest mortality, when localization is trying to

take place, and when trauma to the peritoneal cavity is likeliest to be harmful. We are not convinced, however, that this dangerous period can be recognized by the day alone. All the data that reflect how well or how badly the patient is handling his infection must enter into the decision, as must the surgeon's personal ability to do a nontraumatic operation. Certainly, no oversimplified rule can be blindly followed as a guide to treatment. We believe that some of these 11 fatalities could have been prevented by a choice of treatment better fitted to the clinical indications.

### *Prolonged Surgery*

Five deaths followed appendectomies lasting from seventy to one hundred minutes. Only 1 of the patients was very ill before operation, yet all 5 died of either peritonitis or pneumonia within five days. We question the judgment of persisting beyond one hour with a difficult appendectomy in the presence of peritonitis. The temptation is all too great, especially among the younger surgeons, to allow personal considerations of pride to obscure the main issue of the patient's welfare, once appendectomy has been started. Some of these deaths might have been avoided had the surgeon made a gentle investigation, satisfied himself that appendectomy would be technically difficult and time-consuming, and then elected the lesser risk of draining the region of the appendix and ochsnerizing the patient until a safer time.

### *Errors in Technic*

Six patients who were not very ill before operation nevertheless died promptly of general peritonitis following operations that were neither unduly prolonged nor unwisely timed. The presumption is that rough handling, unnecessary exposure of intestines, unjustifiable packing of gauze into the abdomen and other technical crudities resulted in breaking down delicate protective barriers, with resultant wide dissemination of sepsis in the peritoneal cavity. To whatever extent these presumptions are true must the above six deaths be considered avoidable deaths.

### *Unavoidable Deaths*

Fourteen deaths apparently could not have been prevented. Ten patients were moribund on admission and failed to respond to Ochsner treatment reinforced by transfusions, Wangensteen drainage and other well-chosen efforts. Four other patients died during convalescence from successful operations, 3 of pulmonary embolism and 1 of acute nephritis.

Nineteen deaths were probably unavoidable, although not so clearly so as the above. This group

comprised deaths from pneumonia, pylephlebitis, gas gangrene, septicemia, epileptiform convulsions, acute respiratory failure, acute cardiac failure and peritonitis.

The remaining 11 deaths may or may not have been preventable, the circumstances admitting no presumption either way.

In conclusion, it should be emphasized that all 71 deaths were avoidable in the sense that earlier diagnosis and treatment of the 444 cases of acute appendicitis would have obviated the dangerous and difficult problems of peritonitis and its complications.

## SUMMARY AND CONCLUSIONS

The use of a clinical in place of a pathological basis of classification in a statistical review of 444 cases of appendiceal peritonitis without palpable mass formation has furnished guides for more accurate appraisal and hence more satisfactory individualization of treatment in such cases.

The great majority of deaths are due to progressive generalized peritonitis. The ability to recognize in advance the cases in which localization will or will not take place and to select the safest time for operation in each case, together with good preoperative and postoperative care and a minimum of trauma to the peritoneum, will determine the success of treatment.

The following conclusions seem justifiable:

Patients who look ill on admission and are operated on more than six hours after an incident interpreted as an acute perforation suffer the highest mortality (50 per cent).

A general appearance of being very ill is the most unfavorable prognostic sign, and absence of audible peristalsis is next in importance.

A pulse rate too rapid for the leukocyte count that accompanies it (leukocyte-pulse index over 6) is the most unfavorable prognostic laboratory observation.

The fourth and fifth days of the disease are the most dangerous for appendectomy (22 per cent mortality), the first day is the least (6 per cent). After the fifth day the mortality diminishes to about 9 per cent.

For incision and drainage alone, the McBurney type of incision is more than twice as safe as a medial type of incision. For appendectomy, the type of incision is of less consequence than the amount of trauma done through it.

About half the residual abscesses following appendectomy regress spontaneously.

- Appendectomy lasting between fifty and sixty minutes results in about half the mortality rate of either longer or shorter operations

The proper use of cigarette drains is satisfactory and safe.

When the diagnosis is in doubt and the con

templated treatment is incompatible with recovery from acute appendiceal peritonitis, a fatality may sometimes be avoided by a preliminary gentle exploration through a small McBurney incision.

*(To be concluded)*

## BOSTON MEDICAL LIBRARY

### REPORT OF THE PRESIDENT FOR THE YEAR 1941\*

ALTHOUGH there appears to be no definite provision in Article XVI of the by laws, which prescribes the order of business at the annual meeting, for a communication from the president, perhaps under "Incidental Business" it may be appropriate for him to report on the "State of the Library" with a view especially to telling of the needs and planning for its greater usefulness and prosperity in the future

He who attempts to appraise an institution without first exploring its history is likely to fail truly to understand its character and significance, and I should therefore like to recommend to all of you as "required reading" the fascinating account by our late Librarian, Dr. Farlow, of the efforts, during one hundred and fifty years, of the physicians of Boston to secure the advantages of a medical library. With the passion of our forebears for education, it is likely that, quite unknown to us, groups were formed to share the half dozen medical and scientific journals, and the few medical volumes brought to this country from abroad. The Medical Improvement Society, organized in 1803 by men many of whose surnames may be found on our roster of today, gathered together books that they held under a statute of 1798 as the Second Social or Boston Medical Library, these volumes were housed at Dr. John Fleet's, and a little later at the apothecary shop of Amos Smith, 39 Marlboro Street (now near the corner of Washington and Milk streets). Among the moving spirits, as anyone would predict, were young John C. Warren, treasurer and later librarian, and his friend James Jackson. A list of the books at this time shows twenty-nine titles. Young Dr. Warren was giving a course in anatomy in rooms over White's apothecary shop at 49 Marlboro Street (Washington Street, near the corner of Franklin), and since he was librarian of the little library, it was natural that the books should be moved there from Smith's apothecary shop. At about this time, 1810, the Harvard Medical School, consisting of the persons

of Dr. John Warren, Sr., Dr. Benjamin Waterhouse and Dr. Dexter and their lecture notes, was transferred there from Cambridge. Moreover, Dr. Thomas I. Parker, who had become librarian of the little collection, had his private office at the same address. Later, in 1819, after the medical school had moved to Mason Street, the Boston Medical Library accompanied it to that building, so that it was housed and doubtless closely identified with the school at these two locations, and probably in the latter building was actually united with whatever books had been collected by the Massachusetts Medical College, as the future Harvard Medical School was then called. But the faculty, for reasons now unknown, apparently allowed the alliance to lapse, and in 1826 the accumulated two thousand volumes of the Boston Medical Library, appraised at \$4500, were conveyed to the Boston Athenaeum, which was absorbing various circulating libraries of Boston to enrich its collections, and the thirty-one physicians who, of the seventy-one in Boston, were members of the Library became proprietors of the Athenaeum. Thus, after an adventurous existence of twenty three years, the Boston Medical Library lost its corporate identity, and even its name lapsed as designating a group of books on medical subjects in the Athenaeum. At least two other futile attempts—one by the Observation Society in 1848 and another by the Suffolk District Medical Society—to start a library indicate the need felt by Boston physicians for such an institution.

This was the situation when Dr. James R. Chadwick, thirty years of age, recently returned from Europe, became obsessed with the idea that some at least of the advantages of study abroad could be secured for the doctors of Boston by the establishment of a working and reference library. A preliminary meeting was held on December 21, 1874, and a second meeting one week later, at the office of Dr. Henry I. Bowditch. Final organization was accomplished on August 20, 1875. With the names of those present as a text might be written the history of medicine

\*Read at the annual meeting of the Boston Medical Library, March 3, 1942.

in Boston: Bowditch — anti-slavery agitator, co-discoverer with Dr. Morrill Wyman of paracentesis of the thorax, one-time Jackson Professor of Clinical Medicine, founder of the Society for Medical Improvement — was the first chairman of the first board of health established by any state in the Union; Oliver Wendell Holmes was Parkman Professor of Anatomy and already a great figure among New England literati; Samuel A. Green had a splendid Civil War record and was a historian, a man of letters and later to be mayor of Boston; and Francis Minot was Hersey Professor of Theory and Practice. Associated with these elder statesmen of medicine was a group of younger men of from thirty to forty years of age, including Thomas Dwight, F. I. Knight, R. T. Edes, Henry P. Bowditch, Clarence J. Blake, Charles P. Putnam, C. E. Stedman, William L. Richardson, Edward H. Wigglesworth, Reginald H. Fitz, Francis W. Draper, E. J. Forster, James B. Ayer, A. Lawrence Mason and Oliver Wadsworth — young, enthusiastic, almost to a man destined for high teaching positions, often of professorial rank, in the Harvard Medical School. Holmes was chosen president, Wadsworth secretary, Mason treasurer, and Chadwick librarian.

In October, 1875, two rooms in the basement of 5 Hamilton Place, opposite the Park Street Church, were secured and fitted with two tables, thirteen chairs and some bookshelves. Chadwick's zeal secured the exchanges of the *Boston Medical and Surgical Journal* and the collection of the Society of Medical Observation; the libraries of Dr. George Hayward, clinical professor of surgery, Edward H. Clarke, professor of materia medica, and George Cheyne Shattuck, founder of the Shattuck Professorship of Pathological Anatomy, poured in and were piled on the floor. Soon, there was scarcely room for readers, and the invincible enthusiasts begged and subscribed more money, placed a mortgage and purchased a little house at 19 Boylston Place, once the home of the philanthropist, Dr. Samuel Gridley Howe and his wife Julia Ward Howe. At the dedication ceremonies on December 3, 1876, addresses were made by the president, Dr. Holmes, Dr. John Shaw Billings, librarian of the National Medical Library in Washington, Professor Justin Winsor, librarian of Harvard College, Dr. George H. Lyman, president of the Massachusetts Medical Society, Dr. Calvin Ellis, dean of the Harvard Medical School, Charles W. Eliot, president of Harvard College, and Dr. Henry I. Bowditch. These names are set down as the best indication of the importance ascribed to the occasion by the intellectual leaders of the community.

In the new location, more accessions poured in. From the Massachusetts Medical Society came fif-

teen hundred items; from the library of Dr. J. Orne Green, seven hundred volumes; from the Harvard Medical School, its collection of periodicals and many books, in exchange for duplicate textbooks; and from Dr. Calvin Ellis, late professor of clinical medicine and dean of the Harvard Medical School, his valuable library. By 1886, ten years after removal to the new location, the building was becoming overcrowded. Drs. F. C. Shattuck and Charles R. Putnam established a directory of nurses, which found office space in the library, for which it paid a welcome rental. The councilors of the Massachusetts Medical Society began to meet in the reading room. A possible solution was seen in the proposed inclusion of the library in the new building of the Harvard Medical School at the corner of Boylston and Exeter streets, but the project was not deemed feasible. When Holmes, three years before his death, presented nearly a thousand volumes and caused to be built the bookcases to house them, when the Boston Athenaeum gave its entire medical collection, including the two thousand volumes formerly belonging to the Second Social or Boston Medical Library, which had reposed on its shelves for seventy years, and when the libraries of Edward Wigglesworth, Henry J. Bigelow, Conrad Wesselhoeft and many volumes from the Warren family were added, the problems of overcrowding and of financial support became as acute as ever. How these were solved for a time by generous gifts and bequests and by the building in 1900 of our present splendid house on the Fenway, how we have been enriched by the William Norton Bullard and by the Hyams collections of incunabula and manuscripts, and how portraits, engravings, letters, medals and medical memorabilia have been entrusted to us for posterity constitute a story too long to tell here. Our plant cost half a million dollars; our books and treasures are carried at an equal sum, but are, of course, actually irreplaceable. We stand fourth among the medical libraries in America.

Our past, at least is secure, but what of the future? It occasions your trustees grave anxiety. The Library looks well nourished and presents — with some reservations — an outward appearance of health, but its intimate advisers know that it is anemic and that its vital organs are suffering from financial anoxia. It is operated on an annual income of less than \$32,000 of which less than half is income from an endowment that has suffered serious capital depletion, less than a third is from dues, and the rest is from rental of space and from gifts and miscellaneous sources. We have never been able to complete the stacks, periodical room and other facilities for which our new addition — built with funds raised by the campaign of 1929-1930 — was designed. Thousands of books are

piled in the basement awaiting shelving or other disposition, hundreds of volumes of periodicals are unbound and wrapped for preservation in paper or temporary covers. Thousands of bindings should be renewed. Our salaried staff—but five in number—are numerically inadequate, devoted though they are. Our director, completing his fiftieth year of continuous service, must be supposed to be mortal,—ageless though he seems,—and his accumulated experience and knowledge should be communicated to a young associate. Our fellows—now some eight hundred in number, have diminished by one hundred during the past year. Most of them have shown a loyal spirit of support, like the late George Craigin, who—although long retired—rounded out fifty years of membership, finally terminated by his recent decease. But surely there must be twice as many physicians in Greater Boston and New England who would offer support did they realize our need. Perhaps our very liberality in opening our doors and reading rooms to any reputable citizen, whether or not a physician, has lightened our purse. Furthermore, our marrow has been stimulated recently by radical therapy, which—however optimistic we may be—must be considered fortuitous and not dependable so far as the future is concerned. The bequest of \$25,000 by Dr. Holmes's daughter, subject to a life interest of her brother, Justice Holmes, became available recently and was devoted to the payment of debts and to needed renovation of our building; half the \$10,000 bequest of Dr. John W. Farlow, our second librarian, was spent on repairs; two thirds of a similar sum, a gift from the family of our first secretary, Dr. Oliver F. Wadsworth, and of his son Richard—a later treasurer—was used in renovation and furnishings, and most unpredictable of all, the WPA carried out a splendid project of sorting, classifying, cleaning, cataloguing, boxing and shelving that represented a money value of \$75,000. Idle hands now find other occupation.

Perhaps, in these paragraphs, you have gained a true impression of our library in its earlier years, as an institution sorely needed by the closely knit medical profession of its time, supported by the mental and actual manual labor and by the purses of most of the physicians of Boston who amounted to anything, closely associated with the Harvard Medical School and its graduates because there were no others, and subject to no rivals as a source of medical literature. Great changes that have since occurred pose new problems. Fortunately for Boston and New England and the world at large, the medical schools of Boston University and of Tufts College have been born and have

prospered, and each takes pride in a working library of its own. That of the Harvard Medical School—necessarily with powerful support—has grown by leaps and bounds. Each hospital maintains its library for the use of staff and interns and nurses. Moreover, the individual physician receives from two to ten or more periodicals,—depending on the societies to which he belongs and his special interests,—which, with their abstracts, supply him with all the current medical information he can absorb. There is danger of—indeed there exists—duplication of effort, which is wasteful, and division of support, which is unfortunate. Let it be emphasized, however, that among the various medical libraries exists cordial co-operation: several hold “professional membership” in our library and constantly make use of the privilege of supplementing their books of reference.

Confronted by these facts and tendencies as they have developed over the years, your trustees have given *serious consideration to various proposals*, involving usually some form of alliance or amalgamation, with increased opportunity for service. Sixteen years ago, a plan for an academy, with our library as its nucleus, advanced to a point where a charter was obtained, and tentative plans were drawn. Of this project and the reasons for its failure, your president has no personal knowledge. Once more, however, the subject is ripe for review, especially because there is available an illuminating survey of the medical libraries of Boston, with recommendations for the future, from an authoritative source.

Through the good offices of the director of the Harvard University Library, the Carnegie Corporation financed the commission of Mr. Thomas P. Fleming, medical librarian of the College of Physicians and Surgeons of Columbia University, to examine all our medical libraries, to confer with a committee and make a report with recommendations. The work was done during the summer and autumn of 1941. Mr. Fleming made an elaborate factual survey of eleven libraries, with their many subordinate units, and the committee made a report that has been appropriately distributed. The findings that especially concern us are as follows:

That the Boston Medical Library is centrally located and has sufficient storage space for many years to come; . . . that because of lack of funds it is understaffed and does not furnish the type of service, in regard to either quantity or quality, that is to be expected; . . . that its future—particularly in view of present-day attempts to eliminate decentralization and duplication—hinges about its development as a *reference library*, not only for the benefit of Boston and its immediate vicinity but also for the rest of Massachusetts and other New England states.

The recommendations made by the committee include:

That the staff of the Boston Medical Library be increased, to provide adequate and efficient service; . . . that all working libraries co-operate with it . . . and use it to best advantage as their reference library; . . . that either (a) a very substantial sum of money be obtained to erect a new building, to be known as the New England Academy of Medicine, which would house not only the Academy but also the Boston Medical Library and the Massachusetts Medical Society, including the *New England Journal of Medicine*, or (b) a substantial sum of money be obtained . . . to make the necessary alterations in the Boston Medical Library to provide attractive modern facilities and adequate stacks, and to cover in part, through increased income, the additional expense incurred by increases in its staff; . . . that the financial support of the Boston Medical Library by the working libraries be increased, in view of the improvement in service rendered to them

and of the opportunity to cut down on their annual expenditures.

Already, plans are made by a group of men, among whom representatives of our library are conspicuous, to explore every possibility and to devise and later attempt to execute a comprehensive, broadly conceived plan for the future. As a Nation, we are literally in a death struggle with an implacable, relentless and powerful foe whose purpose is to enslave us, and it is quite likely that many of us may say that this is no time to bother about matters that seem to have no relation to the struggle we are making to win the war. Surely on further thought, however, every man of us will realize that this is the time of all others when we must guard and hold fast that which is good and has been amply proved to be a source of strength and inspiration.

DAVID CHIEVER, *President*

## REPORT OF THE LIBRARIAN FOR THE YEAR 1941\*

THE year 1941 saw the Boston Medical Library pass from a period of national emergency to one of war. Libraries pass through wars, except when destroyed, as some of our sister institutions in Great Britain and elsewhere were, less affected than many of our national foundations. Our stock in trade, books, still retain their influence even if uprooted and transferred to other quarters. Certain of our most valuable possessions have been moved to places of comparative safety, where they are still available but not so prominently displayed. The very moving has been helpful in recounting our treasures and will probably lead to a recataloguing of our most valuable books. Our incunabula in the Bullard Collection were last catalogued in 1929. Since that date, this one group of books has tripled in size, and to them have been added others in the Hyams Collection. Our manuscripts have also grown in number, and it now seems fitting to print a new list of all the manuscripts and books in the library known to have been issued before 1500. Such a volume is indeed contemplated. Fortunately, too, this year will see the completion of fifty years of service to the Boston Medical Library by Mr. James F. Ballard, whose knowledge of these books is outstanding. To him must fall the work of compiling the catalogue, but to the fellows and friends of the Library comes the opportunity to honor a man devoted to our interests.

The war has brought, as might be expected, certain changes in our library life. All foreign periodicals, except those coming from Great Brit-

ain and Russia, are now frozen in their respective countries. In some instances, before the mails closed down entirely, arrangements were made to hold periodicals for future delivery. Except for a few issues, presumably lost in transit, English periodicals are received regularly. During the year, large shipments of medical magazines were received from Russia by exchange for duplicate American journals. In view of the lack of foreign journals, the usual gifts for their purchase from the local medical societies were not solicited during the year. However, gifts for periodicals were generously donated by the New England Pediatric Society and the Greater Boston Medical Society.

The national emergency also closed, on June 30, our two projects of the Works Progress Administration. Much, however, had been accomplished, particularly in sorting and classifying our theses and in putting our catalogue in shape. The *Union Catalogue*, fortunately, was practically completed, except for typing of the cards. This additional portion, essential to make the catalogue useful, awaits only additional funds. Although the projects have stopped, we can regard the work done as a definite contribution of considerable value to the Library. One of the aspects, moreover, is being carried on to completion. The Boston Medical Library catalogue cards are being copied, as agreed, for the library of the Harvard Medical School. This is about half finished. The proposed binding project, also to be under the Works Progress Administration, was never begun. Certain binding apparatus, purchased in anticipation

\*Presented at the annual meeting of the Boston Medical Library on March 3, 1942.

of the project, is a valuable accession to the Library. It is always salable, but will be held for the time being.

The war, also, has caused a change in our hours of opening and closing the Library, owing to a curtailment of oil used for heating. The hours were greatly restricted at one time, along with those of our tenants and our neighbor, who buys heat from us. Later in the year, we were able to lessen the restriction on hours, and at the present time we are open for a normal period.

Attendance and circulation have been maintained at approximately the same level as in 1940. The circulation, as was noted last year, is 25 per cent greater than it was in 1939. Ten thousand more books, pamphlets and bound or current journals are thus handled each year by our small staff, a heavy drain on their energies and good nature. In addition, our interlibrary loans have jumped from 219 items to sixty-two libraries in 1939 to 633 items to one hundred and twenty libraries in 1941. The assembling, the packaging, the arrangements for fees and their collection, the answering of correspondence and the supervision of these loans are a not inconsiderable added burden on the reference librarian. If the call for books, moreover, both by our readers and by loan, is kept up as the years go by, we shall be faced with an even more acute problem than we have known about for years. Our staff is too small to give adequate service.

In 1941, we added 2432 volumes to our store of books, somewhat less than in previous years. This is largely due to the decrease in volumes of periodical literature received owing to war conditions: only 582 volumes in 1941 as compared with 1995 volumes in 1939. The number of books acquired has actually increased from 1432 to 1824. Thus, our library grows in both stature and usefulness each year, but at the same time the labors of our staff are increasing. If we seem a little "short," we are just trying to put quarts into pints, or as Osler would say, we are driven from Dan to Beersheba.

A number of papers have been published by the staff, directly related to the Library. The director issued his annual report, "The Medical Books of 1940," in the *Bulletin of the Medical Library Association* for June. The Librarian's "Report for 1940" was printed in the *New England Journal of Medicine* for May 22, and he also published two historical papers based on our collections, "The War of 1812 and the Marine Hospital for the Port of Boston," in the *Bulletin of the History of Medicine* for June, and "The Problem of the Three Edward Warrens," in the *New England Journal of Medicine* for June 19. The death of Sir D'Arcy Power on May 18, an old friend of the Library, and indeed of all medical libraries and

historians, was noted in an exhibit of books, pamphlets, pictures and letters in the rotunda and an obituary in the *New England Journal of Medicine* for July 3.

The Book Review Department, thanks to the generosity of the *New England Journal of Medicine* and our fellows and friends who review the books, continues to function in a satisfactory manner.

In the last year, the cataloguing of the Storer Collection of Medals has been brought up to date, listing all the accessions since the late Dr. Malcolm Storer issued his catalogue of the whole collection in 1931. Valuable additions have been made in the last few years, particularly the twenty nine large plaques designed by Pierre Jean David (1789-1856), usually called David d'Angers. This French sculptor worked in Paris at the beginning of the nineteenth century. Many famous men and women sat for him. A nearly complete collection, originals and copies, is in the Musée David at Angers. Of particular interest is his monument to Gutenberg at Strasbourg. The medallions in our collection are of contemporary physicians, many of them well known in the history of medicine.

In 1941, our special collections were increased by modest accessions, largely through purchase by funds set up for the purpose. We have added twoscore incunabula to our growing list, now widely recognized as a group of books of national importance and becoming more widely used each year by scholars. American, English, Spanish and other imprints have been acquired, helping to round out our collection in fields of particular interest.

Of all the book auctions and sales that occurred in 1941, two have particular interest for us. On three days in June, the library of Sir D'Arcy Power was sold at auction by Sotheby and Company, of London. We received only four items out of two-score bid for by cable. The prices in general were well maintained, some of the items selling for high figures. We obtained a good copy of the 1585 edition of Clowes's, *A Brieve and Necessary Treatise . . .*, and the first collected (1639) edition of John Woodall's *The Surgeons Mate . . .*

Another and still more unusual sale occurred at Gimbel Brothers in New York City on October 27. Many of the books offered were sold before the sale actually opened, and fortunately we had arranged with a New York dealer to purchase four books for us. The most significant was the *Prognosticon* (1483) of Dominicus Maria de Novaria, the only copy in America. The books were offered at bargain prices marked with sums such as \$197.50. It seems unlikely that incunabula have ever been sold in a department store before.

The collection was part of the books assembled by O. H. F. Vollbehr, another section having been previously disposed of to the Library of Congress.

As usual, there have been special donations to the Library in 1941. One of the most important is the watch formerly owned by Dr. Amos Holbrook, of Milton, the vaccinator, and his honorary diploma of 1814 from the Massachusetts Medical Society.

In previous years, the Librarian has pointed out a course for the future growth of the Library and its sister institutions. Plans must be held in abey-

ance in wartime, but this does not mean that such plans should be abandoned. The whole library situation in Boston still presents the same problem and will do so even more acutely after the completion of the war. It is well to retain in mind the basic principle of a central reference library, with working units in various medical schools and hospitals. Only on such a broad foundation can the problem be solved. In this solution, the Boston Medical Library should ever retain a vital interest.

HENRY R. VIETS, *Librarian*

## UNRECOGNIZED TYPHOID CHOLECYSTITIS AS A SOURCE OF HOSPITAL INFECTIONS\*

A. DANIEL RUBENSTEIN, M.D.†

BOSTON

**A**CUTE infection of the gall bladder complicating the course of typhoid fever has frequently been noted since the report of Gilbert and Girode<sup>1</sup> in 1890. Similarly, the chronic cholecystitis associated with the typhoid-carrier state has been definitely established as a clinical entity. Thus, although the predilection of the typhoid bacillus for the gall bladder has been sufficiently emphasized, a diagnosis of chronic cholecystitis is usually made without the realization that in a definite number of these cases *Eberthella typhosa* may be the etiologic agent. When such patients are admitted to surgical wards for operative procedures, hospital personnel are exposed to unrecognized typhoid carriers for varying intervals of time. Similarly, in rare cases, acute cholecystitis complicating typhoid fever may also find its way into hospitals without recognition of the basic etiology. The recent epidemiologic investigation of two such hospital infections is considered of sufficient interest to merit discussion.

### CASE REPORTS

**CASE 1.** Dr. R. S., a 25-year-old married house officer, was admitted to the medical service of his own hospital on December 16, 1941, with complaints of malaise, generalized pains and aches, and fever. He had been perfectly well until 3 days prior to admission, when he had noticed that he tired easily. The temperature at this time was normal. In 24 hours, the patient became aware of generalized pains and aches associated with slight soreness of the throat. On the following day, when it was found that the temperature was elevated, he was admitted to the hospital. On admission, physical examination was essentially negative except for diffuse redness of the throat.

Examination of the blood showed a red-cell count of 5,700,000 with a hemoglobin of 96 per cent, and white-

cell counts varying from 3500 to 7300; the blood smear showed 69 per cent neutrophils, 20 per cent lymphocytes, 10 per cent mononuclears and 1 per cent eosinophils. Urinalysis was negative. The blood serum agglutination reactions against typhoid fever showed a gradual rise in titer from + in a dilution of 1:40 on December 17 to ++ in 1:320 on January 6. A blood sample submitted for a Widal test to the State Laboratory was reported positive on December 30. A stool culture was positive for *E. typhosa*.

The temperature remained elevated for about 10 days. The course was mild and uneventful except for an attack of acute right-upper-quadrant pain on December 25. The pain was severe and radiated to the right back and side, and was relieved only after the administration of morphine. The attack was associated with spasm over the region of the gall bladder. Tenderness in the right upper quadrant persisted for 5 days. The temperature became normal on the 11th hospital day. There was no recurrence of gall-bladder symptoms. The diagnosis was typhoid fever.

**Epidemiologic investigation.** To establish a source of infection, attention was directed first of all to the familial contacts of the patient. There was, however, no history of previous typhoid fever among the several members of his own family or that of his wife. Laboratory study of these contacts was entirely negative. The presence of a recent case of typhoid fever on the medical wards of the same hospital was then considered as a possible source of infection. The house officer denied any contact with this case. There was a history of at least two meals away from either his home or the hospital in the month prior to infection. Since no other cases had been associated with the restaurants named, this did not seem an important clue. The possibility of a missed case of typhoid fever was then considered as a source. The patient could, however, recall no recent case of either unexplained fever or peritonitis of unknown etiology. Inquiry was then made regarding patients with gall-bladder disease treated on his wards within the 4 weeks preceding onset. The records revealed 4 such cases during that time. The house officer was particularly aware of 1 patient, Mrs. R. G., who had had an operation for chronic

\*This investigation was conducted in co operation with the Boston Health Department.

†Epidemiologist, Division of Communicable Diseases, Massachusetts Department of Public Health.

cholecystitis and who subsequently had a second operation for stone in the common duct. There was persistent bile drainage following both operations. The house officer had frequently changed the dressings of this patient. In addition, he had helped prepare cocktails for her made from her own bile. The admission and discharge dates in this and in the 3 other recently operated gall bladder cases were obtained. Visits were then made to the homes of these persons, and blood and stool specimens were obtained. Two of these 4 patients gave a past history of typhoid fever. One of these was Mrs. R. G., who had had the disease about 40 years previously. The Widal test and stool culture of specimens from this patient were both positive for *E. typhosa*. Stools in the remaining 3 cases were negative.

**Source case.** Mrs. R. G., a 48-year-old woman, was admitted to the surgical ward on October 20, 1941, with a chief complaint of recurrent upper abdominal pain and jaundice. Her first attack occurred 20 years previously, and was followed by several such episodes for about a year. The patient was then "symptomatic" until about a year prior to admission, when there was sudden onset of jaundice followed in 24 hours by severe cramp-like pain in the upper epigastrium radiating posteriorly to the interscapular region. There were several subsequent attacks, which came on approximately once a month until 4 months before admission. One month prior to entry, attacks began to occur once each week, the last being 17 days before admission. X-ray studies performed by the patient's physician revealed gallstones.

Physical examination showed a slightly jaundiced middle-aged woman in no apparent distress. The only significant physical finding was a minor degree of jaundice of the skin and sclerae. Examination of the blood showed a red-cell count of 4,550,000 with a hemoglobin of 90 per cent, and a white-cell count of 4500, the blood smear showed 59 per cent neutrophils, 32 per cent lymphocytes, 3 per cent mononuclears, 4 per cent eosinophils and 2 per cent basophils. The bleeding time was 3½ minutes, the clotting time 5½ minutes, and the prothrombin time 13.5 seconds. The icteric index was 18. Urinalysis was negative except for an occasional slight trace of albumin. The hospital diagnosis was chronic cholecystitis with cholelithiasis.

On October 22, the patient underwent cholecystectomy. Many stones were found in the common duct. Postoperative cholangiograms confirmed the operator's impression of residual common duct obstruction. The stools were clay-colored at several examinations. There was drainage of about 4 cc. of bile daily.

The patient's condition remained unchanged until November 22, when a second operation was performed, and the common duct was re-explored. Many stones were removed. Following the second operation, there was a large amount of biliary drainage through a T tube and through the wound. The biliary drainage through the T tube persisted throughout the hospital stay and continued even after discharge. Cholangiograms following the second operation suggested a stone in the terminal portion of the common duct. The patient was discharged on December 12, 1941.

**CASE 2.** Miss M. C., a 22-year-old affiliated student nurse, was admitted to the medical ward on January 2, 1942, with complaints of headaches, chills, nausea and vomiting. She had been well until 2 days before admission, when she developed a headache and began having chilly sensations. Later that day, she became nauseated and vomited watery material. The next day, the head

ache persisted. The patient complained of backache. Although she was still nauseated, there were no other gastrointestinal complaints. The past history was not important except that the patient had received a course of antityphoid inoculations early in her training course, approximately 2 years and 2 months prior to the onset of this illness.

On admission, the temperature was 101°F, and the pulse 90. Physical examination was negative except for slight redness of the throat and harsh breath sounds, with scattered coarse rhonchi over both lung fields.

The white cell counts varied from 6400 to 3900. The hemoglobin was 85 per cent, and the smear showed 74 per cent neutrophils and 26 per cent lymphocytes. Urinalysis was negative. Blood culture on January 4 was positive for *E. typhosa*. A positive Widal reaction in a dilution of 1:160 was reported on January 8. The temperature was elevated until January 15. The course was mild, and the patient made an uneventful recovery. The diagnosis was typhoid fever.

**Epidemiologic investigation.** The epidemiologic investigation of this case revealed that the patient had worked, during the 4 weeks preceding the onset of her illness, on a single surgical ward. Inquiry was then made concerning possible missed cases of typhoid fever or surgical cases that might have been of typhoid origin. This brought up for consideration 3 patients with gall bladder disease who had recently been treated on that ward. All 3 had been discharged, and home visits were made to establish a possible typhoid etiology. One, Mrs. S. R., a 28-year-old housewife, who had undergone cholecystectomy on December 7 following a diagnosis of acute cholecystitis, had a positive Widal reaction on January 21. She had been discharged from the hospital on December 27. A stool culture from this patient, taken on January 21, about 6 weeks following operation, was positive for *E. typhosa*. However, the history did not disclose a previous attack of typhoid fever. This, in addition to the fact that she was only 28 years old, made it appear unlikely that the patient was a typhoid carrier. A careful review of her recent hospital admission revealed an acute febrile illness, with symptomatology and a white cell count compatible with the diagnosis of typhoid fever complicated by acute cholecystitis. The student nurse had frequently changed the surgical dressings of this patient following her operation. The discovery of this previously unrecognized case of typhoid fever necessitated the search for the ultimate source of infection among the contacts of the newly discovered case. One such contact, her 64-year-old mother-in-law, gave a history of typhoid fever 25 years previously. For several years, the mother-in-law had had recurrent attacks of right upper-quadrant pain, together with other symptoms usually associated with chronic disease of the gall bladder. It was also learned that 5 years previously, while she was visiting the family of a daughter residing in Canada, her son-in-law had developed typhoid fever. Laboratory study of this suspect revealed that she was a chronic typhoid carrier and was therefore the source of infection for Mrs. S. R., who in turn infected the student nurse.

**Source case.** Mrs. S. R., a 28-year-old housewife, was admitted on December 6 with a chief complaint of right upper quadrant pain of 1 day's duration. About 3 weeks before admission a severe upper respiratory infection, associated with heaviness of the chest and productive cough, appeared. About a week later, the patient noticed that she tired more easily than usual. Her arms and

legs felt heavy. She could scarcely "stand on her legs." After this feeling of tiredness had persisted for about a week, she found her temperature to be 104°F. She consulted a physician, who advised bed rest. The fever persisted. On December 1, she became aware of a dull ache in the right upper quadrant. This subsided until 24 hours prior to admission, when the pain returned with increasing severity. It was intense and colicky, and radiated to the back. She became nauseated and vomited several times. There was no jaundice or clay-colored stools. The past history revealed an attack of right-upper-quadrant pain 1 year previously that had lasted for 3 days.

On admission, the temperature was 103.4°F., and the pulse 120. Physical examination revealed an alert, feverish, restless woman in obvious distress. General examination was otherwise negative except for spasm and tenderness in the right upper quadrant. Examination of the blood showed a white-cell count of 8050, a red-cell count of 4,130,000 and hemoglobin of 70 per cent. Urinalysis was negative. The icteric index was 11.

On December 7, the gall bladder was removed under spinal anesthesia. It was tense, edematous and inflamed, with several small areas of necrosis. No stones were found.

Following operation, the patient ran a spiking temperature. On December 9, 2 days after operation, the white-cell count was 9000. The temperature on that day was 101.4°F. The temperature gradually subsided and was normal on December 24. Except for the temperature, the course was uneventful, and the patient was discharged on December 27. The hospital diagnosis was acute cholecystitis.

### DISCUSSION

The epidemiologic investigation in Case 1 revealed that a house officer on a surgical ward developed typhoid fever following contact with a patient with chronic cholecystitis who was subsequently found to be a typhoid carrier. Investigation of Case 2 showed that a student nurse on a surgical floor in another hospital had developed the disease while taking care of a recently operated case of acute cholecystitis, which was found actually to be typhoid fever manifested by acute cholecystitis. The symptoms associated with the acute gall-bladder attack distracted attention from the basic disease, typhoid fever. The occurrence of acute cholecystitis as the outstanding feature of typhoid fever has been reported in the literature.<sup>2</sup> It has also been shown that acute involvement of the gall bladder, which is occasionally associated with typhoid fever, may progress to perforation.<sup>3</sup>

It has been demonstrated that stool cultures submitted by typhoid carriers subsequent to cholecystectomy become negative in most cases within a few days to three weeks after operation.<sup>4</sup> However, the stool culture may remain positive for a much longer time and may eventually become negative. In the source case, Mrs. R. G., a positive stool was obtained as late as seven weeks after the second operation. All subsequent cultures of the stools and bile, including those grown in an enrichment medium, have been negative. Thus, the

evidence indicates that the carrier condition in this case has been cured.

It is difficult to say whether or not the stool culture obtained from the second source case, Mrs. S. R., will continue to be positive. Since the gall bladder has been removed, it is very likely that she will become noninfectious in a short time. One wonders whether she might have become a carrier if the operation had not been performed. Garbat<sup>5</sup> showed a high incidence of carriers among patients with typhoid fever who manifested symptoms of cholecystitis either as a complication during the disease or as a sequel during convalescence.

It is an interesting coincidence that a similar mode of infection should have been demonstrated in 2 cases of typhoid occurring within a few weeks of each other in two different hospitals. This raises the question of how often typhoid bacilli are associated with chronic disease of the gall bladder. Isolated reports demonstrating this relation are not infrequent. In 1941, Botsford<sup>6</sup> reported a patient with suppurative cholecystitis who, on admission to the hospital, was found to be a chronic typhoid carrier. Too much reliance cannot be placed on older studies that attempted to demonstrate the frequency with which typhoid bacilli occurred in chronic disease of the gall bladder. It is to be expected that improved bacteriologic technics will be more successful in culturing this organism. More recently, Dickinson<sup>7</sup> stated that in a study of the bile of patients coming to operation for gall-bladder disease it was found that 10 per cent are of typhoid origin. A similar study is now being carried on by the Massachusetts Department of Public Health.

It has been demonstrated that cholelithiasis frequently accompanies chronic gall-bladder disease of typhoid origin. Garbat<sup>5</sup> reported in 1922 that stones were found in 3 out of 21 cases that went to operation. Förster,<sup>8</sup> in an analysis of several hundred carriers, found the same proportion of gall-stone sufferers. However, criteria for the carrier state are more rigid today than they were twenty or thirty years ago. Many patients formerly classed as carriers are now considered convalescent typhoid cases. Thus, Bigelow and Anderson,<sup>9</sup> in 1933, noted that, in 12 carriers coming to operation, stones were found in all. The question of the cause of stone formation in typhoid gall-bladder carriers is beyond the scope of this paper. However, the symptoms associated with the presence of gallstones often serve as a valuable lead to the epidemiologist attempting to seek out a source of infection among the contacts to a case of typhoid fever.

The protection of hospital personnel against typhoid fever is a problem that deserves consid-

erable attention. The unrecognized case of typhoid cholecystitis is not the only form of surgical typhoid that finds its way into hospitals without a realization of the typhoid etiology. Typhoid fever is protean in its clinical manifestation. At present levels of incidence, typical cases are uncommon. Of those reported, many are decidedly unusual in their clinical manifestations, and as a result, a patient may be hospitalized for many days before a diagnosis is made and proper precautions instituted to prevent secondary cases.

For many years, it has been a recommended procedure in hospitals to inoculate members of their personnel, including physicians, nurses, laboratory workers and ward attendants, against typhoid fever. In addition to the primary series of three injections, a stimulating dose of 0.5 cc must be administered each year to maintain a sufficient degree of immunity. Recent reports from the Army Medical School<sup>10</sup> indicate that 0.1 cc of typhoid vaccine, given intradermally as the stimulating dose, offers an excellent level of immunity. The intracutaneous route eliminates practically all the constitutional reactions. The intradermal method has also been advocated by some<sup>11</sup> as the method of choice for primary inoculation. However, all observers<sup>12</sup> are not in accord concerning the superiority of the intradermal route. It is still generally recommended that the initial series of three injections be given subcutaneously.

In Case 2, the patient had received the initial series of typhoid inoculations two years and two months previous to the onset of the disease. The stimulating dose had not been administered. One wonders whether the mildness of the clinical course may have been the result of previous immunization.

The house officer, Case 1, had never received antityphoid inoculations. It is apparent that many interns in Massachusetts hospitals do not receive the protection afforded by typhoid vaccination. Whereas immunizing procedures for nurses are often carefully supervised, house officers are left to shift for themselves in this respect. When schedules are drawn up to immunize hospital personnel, it is essential that house officers be included.

In the management of gall bladder cases on hospital wards, attention must be given to the possibility that a definite number may be of typhoid origin. The practicability of routine stool cultures on all such cases has not yet been definitely established. Further studies, utilizing modern cultural methods, will demonstrate what yield may be expected by this method of attack. The possibility of employing the Widal reaction as a screen merits further investigation. According to this procedure, stool cultures would be submitted only by patients who show some

reaction in the Widal test. At present, a practical approach is to establish in every case of gall bladder disease whether there is a history of typhoid fever or of an unexplained fever consistent with this disease. Whenever a case of chronic cholecystitis presents a past history of typhoid fever, the patient should be kept on precautions until laboratory studies exclude the carrier condition. When such cases are admitted to hospitals for elective surgery, it is preferable that the laboratory work be done prior to hospital admission. In many cases, it will be found that the history of typhoid fever dates back many years. Such an interval does not exclude a carrier condition, since it has been shown that the carrier state may exist for an indefinite number of years until cured by operation.<sup>13</sup> Since a fair proportion of chronic carriers do not present a past history of typhoid fever, extreme care should be exercised by all persons handling dressings and discharges from all gall bladder cases. Hospital personnel in charge of these cases must constantly bear in mind that a certain proportion of all cases of chronic cholecystitis are of typhoid origin.

#### SUMMARY

Two cases of typhoid fever that occurred among the personnel on the surgical wards of two different hospitals are presented. The epidemiologic investigation of the first case revealed a previously unrecognized typhoid carrier as the source of infection. The carrier had been admitted for operation with a diagnosis of chronic cholecystitis and cholelithiasis. The epidemiologic investigation of the second case revealed as the source of infection a missed case of typhoid fever admitted to the hospital for a complicating acute cholecystitis; this primary case was in turn traced to a chronic carrier, the ultimate source.

Protection of hospital personnel by routine antityphoid inoculation is an essential preventive measure in all hospitals.

When cases with gall bladder disease are admitted to hospitals for operative procedures, careful histories should be obtained regarding previous typhoid fever. In cases presenting such a history, laboratory studies should be instituted to rule out the typhoid-carrier state.

The possibility of typhoid etiology should be considered in all cases of chronic cholecystitis. Acute cholecystitis may in rare cases be the most outstanding clinical manifestation of typhoid fever.

still remaining in the circulation after the injection and the increasing amount of antibody that the organism develops. When the two factors come into a certain relation with one another, serum disease occurs. In most of the cases, serum disease begins between the seventh and fourteenth days and usually lasts from two to seven days. Sometimes, however, the onset is earlier than this, — on the sixth day or on the fourth day, or even on the second day, — when it is referred to as an "accelerated" reaction. When it occurs during the first day, or perhaps during the first hour, it produces a clinical picture that is quite the same as that in the anaphylactic reaction described above. The point to observe is that there is no sharp clinical boundary between the normal response — serum disease — and the more rapid and violent reaction, or anaphylaxis.

The symptoms of serum disease are well known. Urticaria and joint pains, which are the commonest, depend on a sudden edema of the skin or of the joint structures. Edema may also develop in nerves and thus produce neuritis, as reported by Hoagland,<sup>12</sup> Brahdy<sup>13</sup> and Bennett.<sup>14</sup> Lemierre's<sup>15</sup> patient developed cerebral symptoms, with loss of consciousness and aphasia. Clog<sup>16</sup> described several patients who developed abdominal pains severe enough to indicate operation for "appendicitis." Swelling of the mesenteric lymph nodes and hyperemia of the peritoneum were found.

The difference between the two types of response depends on the degree of individual reactivity. In anaphylaxis, the first dose stimulates the production of antibodies, which then persist in the blood or tissues or perhaps in both, instead of disappearing slowly as they do in most cases. In serum disease, antibodies develop slowly during the incubation period and reach their maximum immediately after the clinical symptoms have disappeared. They are often in high concentration and can be demonstrated in various ways — by the skin tests, by the precipitin reactions and by injection of the patient's serum into the skin of a normal person and subsequent tests of the prepared site (this is the so-called "Prausnitz-Küstner reaction"); or the patient's serum can be used to transfer sensitiveness to a guinea pig. This easy demonstration by various methods is quite different from what one obtains in the naturally sensitive person described below.

These laboratory findings easily explain why it is so very dangerous to administer a second dose of serum shortly after the occurrence of a serum disease. The high degree of sensitiveness of these patients is not so very surprising. Freedman<sup>17</sup> reports a typical case, in which a six-year-old boy received a dose of diphtheria antitoxin and ten days later developed serum disease — almost as

expected. Twenty days after that, he was tested at the clinic for his sensitivity by intracutaneous injection of a dose of 0.05 cc. of horse serum. Within two minutes, he developed a generalized urticaria and then severe asthma. In spite of heroic doses of adrenalin and treatment in a Drinker respirator, he died in about eight minutes.

Blotner<sup>18</sup> describes a twenty-two-year-old man who had been given a dose of tetanus antitoxin three years before receiving 1500 units of the same antitoxin intramuscularly. There was no immediate response, but eighty minutes later the patient developed a generalized itching with a rash. Adrenalin was given at frequent intervals, at first subcutaneously and later intravenously. He became cold and clammy. The blood pressure fell to 80 systolic, 40 diastolic. In five hours, the patient was taken to the hospital in an ambulance where fluids were administered in large quantities, and he recovered. This was an accelerated reaction due to the preliminary treatment.

Ferguson<sup>19</sup> reports the case of a six-year-old boy who was injured by an automobile and was given three minims of tetanus antitoxin, followed by a complex barbiturate drug (Evipal) intravenously. He went to sleep but in fifteen minutes suddenly had trouble with his breathing. Twenty-five minutes later, a large wheal appeared at the site of the antitoxin injection and spread all over the arm. Another complex drug (Coramine) was administered, with little benefit. The injection of 10 per cent glucose in saline solution intravenously helped at first so that in two and a half hours the patient was transferred to the hospital ward. An hour later, however, he suddenly stopped breathing. Death was considered to be due to anaphylaxis, but I wonder whether the drugs may not have played a major part. At autopsy, the trachea and bronchi were filled with frothy sanguineous material, and almost all the two lower lobes showed hemorrhagic consolidation.

### *Allergic Reactions*

Allergic reactions occur only in persons who have a certain taint (probably inherited) that gives them a special capacity to develop sensitiveness. They appear to be "naturally sensitive." They usually give a past or familial history of eczema, hay fever or asthma. This is the important group, for serious and sometimes fatal reactions can follow what appears to be the first dose of serum. There may be no history of previous contact with the same foreign substance. The reaction appears to come out of a clear sky except for the fact that further study often reveals the allergic background and the allergic constitution of the patient.

In 1931, I<sup>4</sup> reviewed the cases of several patients who died in a few minutes following a dose of serum that was evidently the first. Since that time, however, many accidents have been reported, but not many of them were fatal.

*Incidence of serum reactions.* How often do serum reactions occur? The literature has been reviewed by Tuft,<sup>20</sup> Zinsser et al,<sup>1</sup> Harten and Walzer<sup>21</sup> and more recently, in a very comprehensive article, by Rutstein and his associates.<sup>22</sup> According to the last authors, immediate serum reactions can be grouped on a clinical basis into three definite classes. Thermal reactions (fever and chills) occurred as the only response in 218 patients, or 9 per cent of the total of 2340, treated with a concentrated, type-specific antipneumococcus horse serum by intravenous injection. Anaphylactic reactions, with itching, urticaria, asthma, angio-neurotic and, sometimes, laryngeal edema, occurred in 5 per cent. Circulatory reactions, with a rapid, thready, irregular pulse, shock and, sometimes, vascular collapse, occurred in 3 per cent. And, finally, miscellaneous reactions—nausea, vomiting, headache, lumbar pain and dyspnea without asthma—occurred in 4 per cent. Combinations of these reactions were observed in an other 10 per cent, to make a total of 32 per cent of the patients who developed reactions of one type or another. In another paper,<sup>23</sup> the same authors point out that reactions of all types are commoner with a history of asthma (455 per cent of 101 cases) than they are without such a history (29.6 per cent of 3114 cases). Obviously, the allergic background is always significant, and one should ask each time for evidences of allergy, such as hay fever, asthma and eczema, in the patient and in his family.

The incidence of serum reaction is shown by many figures in many papers. It is, however, not profitable to study them too closely or to attempt any direct comparison between the different reports. As Fox<sup>24</sup> says, variations in the proportion of reactions depend on many different factors, the degree of sensitiveness of the patient under treatment is one; his age is another. The particular lot of serum used may be a third factor. It is known, for example, that the serum from one particular horse may give a larger proportion of reactions than another lot of serum, and the commercial laboratories accordingly pool the serums from different animals. The route by which the serum is injected changes the figures. In the early days, when Park<sup>25</sup> reviewed the treatment of diphtheria by antitoxin, he found that death due to the serum had occurred in only 5 cases among a total of 350,000 children treated. In those days, the doses were of straight horse serum and were

given subcutaneously in amounts varying from 5 to 15 cc.

The serum treatment of pneumonia is given by the intravenous route, and the incidence of serum disease depends on the quantity injected. Before methods of concentration were employed, this serum was given in quantities of 100 cc. or more, and delayed reactions (serum disease) occurred in at least 90 per cent of the cases. At present, practically all serums are concentrated. As a result, Lord and Heffron<sup>6</sup> have found the incidence of serum disease to be much lower: it occurred in only 20 per cent of 1423 patients recovered from pneumonia with serum treatment. When scarlet-fever antitoxin was used in crude form, serum disease occurred, according to Toomey and Baker,<sup>26</sup> in 38.5 per cent of 283 patients, but when concentrated antitoxin was employed, it developed in only 11 per cent of 524 patients.

Rabbit serum was first used by Horsfall and his associates<sup>27, 28</sup> at the hospital of the Rockefeller Institute as a treatment for pneumonia. In 1937, they treated 22 patients with doses varying from 32 to 268 cc. Twenty one recovered from the pneumonia, and a mild serum disease developed in 12 (57 per cent). In 1938, the same authors, in a report on 67 cases of pneumonia treated with rabbit serum, observed that except in Type 3 pneumonia the mortality was as low as 37 per cent. Serum disease occurred in 40 per cent. This figure, however, was much less than that when horse serum was used in the same hospital. Unconcentrated horse serum produced serum disease in 95 per cent of 100 consecutive cases. Rabbit serum, therefore, not only appears to be better than horse serum as a conveyor of antibodies, but produces serum reactions much less frequently. It should be very useful for patients who need serum treatment and yet are sensitive to horse serum. Volini and Levitt<sup>29</sup> also used rabbit serum. They gave an average of 40 cc. of concentrated antipneumococcus rabbit serum intravenously to 153 patients and found serum reactions in 28 per cent. Wood<sup>30</sup> treated 50 pneumonia patients with quantities of immune rabbit serum varying from 10 to 150 cc. injected intravenously. He observed chills and fever reactions in from 26 to 50 per cent, and serum disease developed later in 41 per cent of these cases—an incidence similar to that noted by Horsfall et al.<sup>27, 28</sup> Meanwhile, one should note that it is not the quantity of total protein that is important: it is the specificity. Fox<sup>24</sup> found that pooled human convalescent serum used for the treatment of scarlet fever produced reactions in only 1 per cent of 420 patients.

Recently, Coghill and his associates<sup>31</sup> have described a method of "despeciating" serum by split-

ting off the carbohydrate complex with enzymes like takadiastase; they contend that the product retains about half its diphtheria antitoxin content, whereas it loses its capacity to sensitize guinea pigs to horse serum. Top and Watson<sup>32</sup> have treated 61 children with despeciated antitoxin. Although these patients were selected deliberately as a bad group presumably sensitive to horse serum, serum reactions occurred in only 10 per cent.

### *Reactions to Tetanus Antitoxin*

Tetanus antitoxin causes reactions that are entirely similar to those after diphtheria antitoxin or antipneumococcus serum. Newell and McVea<sup>33</sup> have analyzed 500 patients who were given prophylactic doses of tetanus antitoxin; 59, or 11.8 per cent, developed some type of reaction. Local urticaria developed in every case at intervals varying from a few minutes to two days. Serum sickness, however, occurred in only 22 patients (4.4 per cent). This low figure is probably explained by the relatively small amount of horse serum injected. Schaeffer and Myers<sup>34</sup> treated a patient who had active tetanus and who was so sensitive to horse serum that even tiny doses could not be tolerated. Despeciated tetanus antitoxin was obtained and was injected in slowly increasing amounts, at first intracutaneously, then subcutaneously and finally intravenously. No reactions occurred, and later it was possible to give 10 cc. of the undiluted material intravenously and with no reaction. A total of 140 cc. was injected in various doses, and the patient recovered.

### **P**REVENTION AND TREATMENT OF SERUM REACTIONS

The prevention and treatment of serum reactions are accomplished best by care in the selection of cases and in the administration of serum. Drugs have been tried, but no one of them is very successful. As a method of prevention, Lucchesi and Bowman<sup>35</sup> gave ephedrine and then combinations of ephedrine and calcium in regularly repeated doses to a group of patients; this regimen was begun at the time when the foreign serum was injected. The incidence of serum disease, however, was only slightly influenced, occurring in 38 per cent of the untreated group of patients and in 33 per cent of the treated group. Horsfall et al.<sup>27,28</sup> have recommended that acetylsalicylic acid (aspirin) be given by mouth just before or at the time of the serum injection, but they do not state the dose or present evidence that it does good.

After serum disease has developed, there is not very much that can be done about it. Furthermore, the effect of any treatment is hard to evaluate because the disease is not always long and one cannot be quite sure that the patient who does well with treatment may not also have done well with-

out treatment. Stout and Kisotchek<sup>36</sup> gave hypertonic glucose to 10 patients with serum disease, with some relief. Foshay and Hagebusch<sup>37</sup> used histaminase, saying that 20 out of 22 unselected patients were relieved by the material, which was given sometimes by mouth, sometimes by intramuscular injection and sometimes by both methods together.

A very thorough presentation of the technical details of this subject, including general rules to be followed in the administration of therapeutic serums, is given in a special article prepared by Fantus and Feinberg<sup>38</sup> for the *Journal of the American Medical Association*. As soon as the principles are understood, these rules become almost obvious. Before any foreign serum is injected, it is essential to ask two questions. The first is, Have you ever had serum given to you before? The reason for the previous dose, the type of serum used and, especially, the presence or absence of serum disease after this earlier treatment are important details. The second question is, Are you allergic? That is, has the victim ever had hay fever, asthma or eczema, or has anyone in his family ever had one or another of these symptom complexes?

A test for serum sensitiveness should always be made. There are several methods. A scratch is made with a sharp needle or knife point through a drop of the serum. It should be controlled with a similar scratch through a drop of physiologic saline solution or of water. An intracutaneous test is much more delicate, but may give false-positive reactions unless the serum is diluted ten or even one hundred times with physiologic saline solution. Again, the test should always be controlled with similar injections of something else, such as egg white in a 1:100 dilution or ragweed extract in a 1:1000 dilution, but saline solution alone usually suffices—made with the same syringe beforehand or, better, with another perfectly clean syringe. With both the scratch and the intracutaneous methods, reactions appear in ten or fifteen minutes as typical urticarial wheals, with sharp advancing borders and surrounding erythema or redness. They should be interpreted with due regard for the control reactions.

One performs eye tests by applying a drop of the serum, diluted 1:10 with physiologic saline solution, directly to the conjunctival sac. When the serum is used undiluted, false-positive, irritative reactions may occur. If the patient is sensitive, the eye becomes red at once, and the reaction may include edema of the conjunctiva. It can be relieved promptly by the instillation of a drop of 1:1000 epinephrine (adrenalin) in watery solution. The intravenous test for sensitiveness has been used by Loughlin, Spitz and Bennett<sup>39</sup> and by

Wood.<sup>30</sup> The former give a small dose (0.1 cc.) of the foreign serum diluted with 5.0 cc. of physiologic saline solution and inject it into the vein slowly. If, during the injection, the blood pressure falls 20 mm. or the pulse rate increases 20 beats, the patient is considered sensitive, and the injection is stopped. One or 2 minims of epinephrine can be injected intravenously through the same needle if severe reactions develop. Wood uses a larger dose, — 1.0 cc. of serum diluted with 20 cc. of saline solution, — and he waits a whole hour for reactions to develop before he proceeds with his therapeutic dose. Obviously, such tests in a highly sensitized patient may result in severe and even dangerous reactions.

The relative value of these different tests — indeed, the real value of any test as an accurate measure of the degree of sensitiveness — is far from clear. In hypersensitiveness, antibodies are attached to cells, and to some cells more than to others. The eye or the skin may be more sensitive, or it may be less sensitive than any other more vital tissues — the bronchial mucosa for example. In an unpublished study in our clinic, Rasch<sup>40</sup> found that the skin test (scratch method) gave good reactions to dilutions of ragweed-pollen extract four to eight times as weak as the lowest strength that reacted in the eye. Tuft<sup>20</sup> has stated that a positive eye test to horse serum never occurs in the absence of a positive skin reaction. Brown and Sechzer<sup>41</sup> compared intradermal and eye tests with rabbit serum in 101 patients in their allergy clinic; in both methods the 1:10 dilution was used. Only 1 patient gave a positive eye test, whereas 32 reacted positively to the intradermal injections, 1 of them being so sensitive that the test alone induced a generalized urticarial eruption. Toomey and August<sup>42</sup> found no fixed relation between the presence or absence of slightly positive skin tests at the time of serum treatment and the subsequent appearance of serum disease. Davis<sup>43</sup> has studied this further. In 200 patients (180 children and 20 adults) ill with diphtheria, she found positive skin tests in 39 per cent. Of those with negative skin tests (61 per cent of the total), 22.1 per cent developed a serum reaction after the administration of antitoxin, whereas of the 39 per cent who were skin sensitive, 28.2 per cent reacted later — the figure was higher, but not much higher.

On the whole, I believe that the history is the vital criterion, but that skin tests should be made as a check on the history. The finding of a positive reaction to horse serum constitutes a significant warning of a danger that is very real. A positive skin test may mean a general sensitivity, but not always, and if the skin reaction is not large it may

be possible to proceed with the treatment, provided that one works slowly and with every precaution. If rabbit or beef serum is available, that can be tried. However, if the reactions to small preliminary doses are severe, one should recognize that to take a chance on the results of failing to administer serum may be better than to kill the victim forthwith. In desperate cases, the patient may be desensitized.<sup>34</sup>

The injection of epinephrine (adrenalin) solution at the same time as the injection of serum, or the addition of epinephrine to a dilution of serum with physiologic saline, is to be considered if sensitiveness is demonstrated. It has two objections: the injection of epinephrine to a nonasthmatic person may induce a severe adrenergic reaction, with shaking, palpitation, rise in blood pressure and even disturbance of the heart rhythm; and the epinephrine may postpone and mask the onset of a reaction until an overwhelming dose of serum has been administered. I believe that epinephrine should not be given until the reaction begins, but that it should then be injected at once. Epinephrine should take effect within five minutes, and the prompt injection of a small dose (0.5 cc. of a 1:1000 dilution) should suffice. To give more than 2.0 cc. of epinephrine hydrochloride subcutaneously in one hour may be dangerous.

#### PREVENTION AND TREATMENT OF TETANUS

##### Prevention

The prevention of tetanus at the time of injury of a person who has not been previously immunized with tetanus toxoid is accomplished best by the prompt administration of tetanus antitoxin, as stated above. However, active immunization with tetanus toxoid, will, it is hoped, be a matter of universal application in the near future. In 1923, Ramon<sup>44</sup> discovered that when diphtheria toxin was treated with formalin, it lost its toxic properties without losing its antigenic capacity, and Descombey<sup>45</sup> found this to be true for tetanus. Ramon and Zoeller<sup>46</sup> published several papers on the use of what they called "anatoxin" to produce active immunity to tetanus in man.

The results from active immunization against tetanus are most satisfactory. Rouques<sup>47</sup> has reported that by May, 1939, approximately 1,500,000 soldiers in France had been immunized with tetanus toxoid, and up to the time of his writing, no case of tetanus had been reported among them. Other and similar reports can be anticipated. When normal subjects are given two injections of alum-precipitated tetanus toxoid at intervals of two to eight weeks, — the average is about a month, — tetanus antitoxin develops in the blood. Gold<sup>48</sup> has shown that the alum-precipitated ma-

terial gives better results than plain toxoid, presumably because it is absorbed more slowly and over a longer period. After the first dose, the response is small, but after the second the antitoxic content increases markedly, as Jones and Moss<sup>49</sup> showed. In an earlier paper, Gold<sup>50</sup> found that this antitoxin content tends to fall again in the course of months. If, however, at the time of injury an additional dose of toxoid is administered to these pretreated persons, the antitoxin returns very promptly, and the titer becomes higher than ever. Since, according to a recent announcement,<sup>51</sup> all United States soldiers are to be immunized against tetanus, only those casualties whose wounds have been grossly contaminated with material suspected of containing tetanus spores will require other than an injection of tetanus toxoid.

Reactions to tetanus toxoid, particularly to the second dose, have caused some difficulty. Anaphylaxis has been reported. In 1940, Cooke and his associates<sup>52</sup> described a forty-four-year-old man with asthma who was given his first dose of tetanus toxoid in June without symptoms. In October, the second dose was followed in fifteen minutes by a constitutional reaction, with severe urticaria, edema of the face and prostration. Skin tests with the pure materials used in making the toxoid were applied, and large reactions were obtained to the peptone used in the broth, as well as to the toxoid itself. In 1940, Parish and Oakley<sup>53</sup> observed a patient who did not give any history of allergy, but who nevertheless reacted in ten minutes in the same way as Cooke's patient did; furthermore, when an intracutaneous test with Witte peptone was applied, another constitutional reaction ensued.

Reactions to tetanus toxoid, however, are not common. Whittingham<sup>54</sup> was able to collect only 14 cases (0.023 per cent) among 61,042 persons immunized with two doses. Hall,<sup>3</sup> who has had a large experience with tetanus toxoid in the United States Navy, says little about peptone as a cause of reaction, but he has observed that one lot of toxoid gave reactions (mostly sore arms) in 50 of 1800 second injections, whereas another lot of toxoid gave no reaction in any of the 743 midshipmen treated. He found that the first lot contained more total nitrogen than the second lot, and that it reacted with the protein color tests. The only difference between the two lots was in the manner in which the alum precipitate had been washed. If the reactions are due to peptone in the broth used for growing this organism, it is very strange that guinea pigs sensitized by Hall's alum-precipitated tetanus toxoid did not react to alum-precipitated diphtheria toxoid or vice versa, whereas members of each group of animals died at once

in anaphylactic shock when reinjected with the original sensitizing material.

Is it always safe to give the second dose of tetanus toxoid? Should one always inject a small quantity of the material into the skin itself, to be sure that there is no reaction, before administering the whole of the second dose? This would be playing safe, of course, but since sensitiveness is so rare and reactions are so few, it is probably sufficient in actual practice to inquire about reactions to the first dose of toxoid and then to consider whether the patient has an allergic history. If there is any doubt, however, a skin test takes only a little time and is very easy to perform.

### *Treatment*

The treatment of active tetanus is always difficult, and the mortality ranges between 30 and 90 per cent according to different authors. As Zinsser, Enders and Fothergill<sup>1</sup> write, "A review of mortality statistics does not impress one regarding the value of antitoxin." They point out: "The effect of antitoxin is probably limited largely to neutralization of uncombined toxin circulating in the blood stream and lymphatics. . . . For this reason, its use as a therapeutic agent is definitely indicated." They condemn the injection of antitoxin either into the spinal canal or into the cisterna, for "to reach the motor cells, the injected antitoxin would have to pass the pial membrane and be absorbed across a large space of tissue." Through the blood stream, however, the serum can reach the motor cells quickly and easily.

Quite recently, three papers described a similar and quite new conception of the treatment of tetanus. These papers were written at about the same time. No one of them refers to the others, and it is quite interesting that each of the authors arrived at about the same conclusions and quite independently. Each uses antitoxin intravenously in large doses and then gives heavy sedation. Vener and Bower<sup>55</sup> advocate an initial dose of 100,000 units of tetanus antitoxin intravenously, and a total dose of about 200,000 units. Of 100 patients, 12 died within the first twenty-four hours of treatment, but of the 88 who survived the first day, only 17 died—a mortality of only 20 per cent. Chapman and Miller<sup>56</sup> give a graphic description of a heroic and victorious struggle with the disease in a boy of ten. They emphasize six principles in treatment. The first is not antitoxin but sedation, and they used large and almost continuous doses of luminal sodium and morphine. The second is surgical removal of the focus, and the third is antitoxin, which they give intravenously in moderate doses, 20,000 to 40,000 units at intervals during the first

few days. Lumbar puncture was used frequently for restlessness and convulsions, evidently because of increased intracranial pressure. Finally, they lay great stress on general care: on oxygen for cyanosis; on aspiration of nasal mucus to clear the airways; on food and water by nasal catheter to maintain nutrition; and on constant attendance by skillful nurses. The third paper is by Spieth,<sup>57</sup> who also uses 30,000 to 60,000 units as a first dose. He too emphasizes heavy sedation and lays great stress on skillful care, with expert attention to every detail of medical and surgical management. In a hospital as large as the Cook County Hospital in Chicago, he advocates special tetanus teams of highly trained nurses. As a result of the new methods of treatment, the danger of tetanus has been modified greatly. The experience in Chicago is a large one, and the conclusions of Spieth deserve attention. Mild tetanus, without convulsions, is not fatal. Moderate tetanus with spasm but without cyanosis occurred in 32 patients, 2 of whom died. Severe tetanus is the real problem. Before the modern technic, 109 patients (95 per cent) died in a group of 114, but with the new methods only 32 (74 per cent) died out of 43. In total, the mortality from tetanus at Cook County Hospital has fallen from 67 to 35 per cent. Whoever is called on to treat a patient with active tetanus should read each of these three papers carefully.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28181

#### PRESENTATION OF CASE

A fifty-three-year-old single clerical worker was admitted to the hospital because of nausea.

She had been in good health until a month before entry, when she developed nausea after eating that was occasionally followed by vomiting. The vomiting occurred as often as three times a week, and was not associated with pain, gaseous distress or other symptoms. The bowels were regular, and the appetite was good, although 10 pounds of weight had been lost in the course of the month. A week before entry, a physician prescribed liver and iron therapy; he told the patient that she had been having "glycosuria for several years."

The patient's father died at fifty-nine years "in diabetic coma."

On admission, the patient appeared well developed and nourished, with striking pallor of the skin. The mouth was edentulous. The breasts, heart and lungs were normal. The abdomen was soft, with a movable mass extending upward from a point just below the umbilicus; this seemed to join with a second mass that lay just beneath the left costal margin. The left border of the masses seemed quite discrete.

The blood pressure was 140 systolic, 90 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 3,150,000 with 8.4 gm. hemoglobin, and a white-cell count of 12,400, with 74 per cent polymorphonuclears, 18 per cent small lymphocytes and 6 per cent monocytes. The blood Hinton reaction was negative. The hematocrit was 33 per cent. The prothrombin time was normal. The urine was normal on two examinations. The stools were guaiac negative.

Roentgenograms of the gastrointestinal tract showed a normal stomach and duodenum. One of the upper loops of jejunum showed pressure of an extrinsic mass; the upper loops were slightly dilated. The two-hour film showed most of the barium beyond a lobulated mass, 15 cm. in diameter, lying in the left midabdomen. One loop of bowel appeared involved by the mass, since this loop retained barium for five hours. The margins

of the bowel were irregular and serrated, and there seemed to be swelling of the mucosa, without definite obstruction. The lower ileum and colon appeared normal, although the mass seemed to press slightly on the upper descending and transverse portions of the colon.

Two days later, additional roentgenograms were taken with a Rehfuess tube passed into the third portion of the duodenum. The first loop of jejunum again appeared dilated. The second loop ran around a mass and showed marked disturbance of its mucosal pattern. No definite folds were seen. Fine sinuses appeared to run away from the lumen. The abnormal area extended approximately 16 cm. The lower small intestine seemed normal, barium reaching the ileocecal valve in twenty minutes.

On the ninth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: I must admit that I have not a great deal to go on in this patient except that she had nausea and vomiting of a month's duration. She was fifty-three years of age and came in with a tumor in the left upper quadrant. The description on physical examination is different from that on x-ray examination, and I think one must realize that in the latter the mass chiefly noted was probably the lower one.

Let us approach this by considering tumors of the left upper quadrant. The first one that enters my mind, since the upper mass was at the left costal margin, is the spleen. I cannot connect the spleen with a mass separate from it and extending below the umbilicus. We have no history of malaria or any other disease that might incriminate the spleen, and I think that the spleen can be ruled out. It is possible that the patient had an aneurysm of the abdominal aorta, but such an aneurysm would not be freely movable and would be a pulsating mass. Therefore, I can rule out aneurysm. It might be a kidney tumor, because kidney tumors can present anteriorly as well as posteriorly, but again we have nothing to incriminate the kidney. The urine examination was negative. No intravenous pyelograms were done, or reported at least; and I therefore think that a kidney lesion can also be ruled out. One must consider a number of conditions in the gastrointestinal tract, but before going on to those I might ask Dr. Holmes to show us the x-ray films. Do you know whether the barium reached the ileocecal valve in twenty minutes after it was taken by mouth?

DR. GEORGE W. HOLMES: I do not believe so. I think the last statement refers to an enema for

the small bowel, which Dr. Schatzki has recently been working on

We have fairly good evidence that this patient had a lesion involving the small bowel and primary either in the small bowel or in the abdomen outside the small bowel. The stomach and colon were normal. There is nothing abnormal about the appearance of the liver and spleen, according to the x ray films. The kidneys are not well visualized. There is no evidence of any disease of the bone. In this first film, one sees dilated loops of small bowel, which are definitely abnormal, and in this one, taken when the barium was leaving the stomach, the loops are rather large and the barium has a tendency to pile up in that area. A little later, one sees retention of barium, and a rather ragged indefinite margin in the same position. In twenty-four hours, there are some traces of barium in the small bowel. From this examination alone, we have very good evidence of a small-bowel lesion. This next group of films, taken after the injection of the barium through the tube, shows a definitely deformed loop of small bowel. Lesions of the small bowel often show quite extensive involvement of the mucosa but do not of necessity produce obstruction. This one did, and there is no question about the involvement of the mucosa. As I read the note, I got the impression that there was some evidence of another lesion in the small bowel, but I cannot find it offhand. The lower small bowel seems to be normal. In other words, I do not believe this is the so-called "ileitis." It does not look like that. It is some form of tumor. It could be tumor outside involving the bowel, or it could be a tumor involving the bowel from the inside.

DR. WILLIAM B. BREED: Can you demonstrate the displacement by the mass that was palpated? I do not see that.

DR. HOLMES: I do not see it either. I think one would have to fluoroscope the patient to be able to visualize it. In these films, it is not obvious.

DR. LINTON: Another condition I had considered is pancreatic cyst, but I believe the fact that the jejunum beyond the ligament of Treitz for a considerable distance is involved rules out the question of pancreatic cyst. Also, the fact that it was movable eliminates, such a cyst, because the pancreas is a rather fixed retroperitoneal structure. The conditions one must consider are: carcinoma, lymphoma, congenital abnormality and infection.

Carcinoma of the jejunum is a fairly rare disease, but it does occur. Carcinoma of the jejunum, however, would produce a localized lesion, with complete obstruction rather than a lesion that extended over perhaps 16 cm of the bowel with only partial obstruction. The other thing

that seems strange, if it should prove to be carcinoma, is that the stools were guaiac negative. Certainly, with an ulcerated lesion, one would expect at least microscopic blood in the stools.

Was this a lymphoma of the small bowel? I am unable to rule it out, and I think that this diagnosis should be seriously considered. The patient had a low red cell count and hemoglobin and not a very significant white cell count.

One other condition that I should consider much more seriously if this were a child rather than an adult is so-called "enteric cyst" or reduplication of the intestinal tract. It seems unlikely that the patient would live fifty three years without getting into trouble from such a cyst, and I think one would have to exclude it on that basis. Then there is the mesenteric cyst, which is different from an enteric cyst or reduplication of the intestinal tract since it is localized in the mesentery instead of involving the bowel wall. That seems to me to be a possibility. The only thing that seems doubtful about that diagnosis is the fact that in the last x ray film fine sinuses appeared to run outward from the lumen of the bowel; this suggests to me that there was destruction of the bowel wall or intestinal mucosa, with sinuses running away from it. I remember a case similar to this in a patient who ate a piece of porcupine quill, which stuck in the upper jejunum and produced an abscess. One can rule out the question of foreign body with abscess because the patient had a freely movable mass, no fever and no leukocytosis.

In conclusion, I believe that this was a lesion of the bowel, involving the bowel wall and the bowel lumen, with partial intestinal obstruction. The only way to be absolutely sure what the condition is is to open the abdomen. I hazard the guess that this patient was suffering from lymphoma of the small bowel.

A PHYSICIAN: Would not the appearance of the serrated small bowel be against anything like cyst?

DR. LINTON: I should think so, except an enteric cyst, and the patient is too old for that.

DR. TRACY B. MALLORY: The X-ray Department expressed a preference for regional enteritis. Do you want to comment any further about that, Dr. Holmes?

DR. HOLMES: I think they had a decided advantage over me, and I hesitate to disagree with them. Of course, with a multiple lesion, enteritis should always be seriously considered.

DR. LINTON: I intended to discuss regional enteritis. It seemed a definite possibility in view of the x-ray picture. The thing against it is the short duration of the history and the localization of the

lesion in the jejunum, although I am aware that it may occur in this location.

DR. CHESTER M. JONES: It tends toward fistula formation.

DR. ALLEN G. BRAILEY: I think we should re-emphasize the points that Dr. Jones and Dr. Richardson made two weeks ago when I discussed a case—namely, guaiac-negative stools do not rule out ulcerative lesions in the mucosa, and furthermore the rather extreme anemia means that the patient had been bleeding, probably for some time.

#### CLINICAL DIAGNOSIS

Lymphoma of jejunum?

#### DR. LINTON'S DIAGNOSIS

Lymphoma of jejunum.

#### ANATOMICAL DIAGNOSIS

Carcinoma of jejunum.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: Dr. Richard H. Sweet, who operated on this patient, is not here. Can you describe the findings at operation, Dr. Brailey?

DR. BRAILEY: The upper 46 cm. of the jejunum was moderately dilated and injected and quite definitely edematous. Then, about 16 to 18 cm. of jejunum was of normal contour but of smaller size, firm, deep red and speckled with implants. The lymph nodes of the mesentery were involved. The second mass described was a large carcinomatous implant in the mesentery.

DR. MALLORY: The preoperative diagnosis was the same as Dr. Linton's,—lymphoma of the small bowel,—but at operation it was obvious at a glance that it was cancer, primary in the jejunum; that diagnosis was proved by biopsy. It was quite beyond the realm of resection, and a side-to-side anastomosis was done to relieve obstruction.

#### CASE 28182

#### PRESENTATION OF CASE

A sixty-year-old housewife consulted a physician because of numbness in the right leg for a week, and because of various "heart symptoms" of much longer duration.

At least twenty years previously, the patient had been told that she had "heart disease," and on one occasion had been refused life insurance because of it. She frequently visited a health resort. On her last trip to that institution, seven months previously, she had been told that she had auricular fibrillation, with a systolic blood pressure ranging up to 165. At that time, she complained of shortness of breath

on exertion, palpitation and precordial soreness. These symptoms persisted. About six months later, the patient noted for the first time an ache in the upper part of the left arm. This remained constant, becoming worse on exertion. After four weeks, there was a very severe exacerbation of this pain. At about the same time, a cold feeling became manifest in the right leg. This was followed by a persistent numbness in the leg, but no actual pain. During this period, the patient took digitalis.

At the age of twelve years, the patient had "growing pains," but she never was aware of frank rheumatic fever. The family history was of interest, in that the patient's mother died following an amputation for an embolus.

On examination, the patient appeared rather pale, with marked engorgement of the neck veins. The heart was enlarged to the left, with the border of dullness 8.5 cm. from the midsternal line in the fifth interspace. A systolic murmur was heard in the aortic area, without associated thrill transmission to the neck. There was a slight systolic murmur at the apex, with a definite presystolic rumble. The pulse was grossly irregular, at 76. The blood pressure was 135 systolic, 70 diastolic, in each arm, although the pulse seemed stronger in the right arm than in the left. The lungs were essentially normal, as was the abdomen. There was slight pitting edema of the shins. The right leg was noticeably colder than the left. Pulsations of the dorsalis pedis artery were palpable in the left foot, but not in the right. Blood-pressure oscillations were present in both legs, less noticeably on the right than on the left.

An electrocardiogram showed auricular fibrillation, with a rate of 70. The T waves were diphasic in Lead 1, with sagging ST segment, but there was marked and deep inversion of the T waves in Leads 2 and 3. In Lead 4, the R wave was present, and the T wave was diphasic. This record was similar to one taken seven months earlier, except for deepening of the T waves, both in Lead 2 and in Lead 3.

The patient was maintained on digitalis and at rest. After two weeks, she experienced sudden onset of sharp pain over the left chest anteriorly. The respirations became shallow, and were accompanied by pain at the left costal margin and in the precordium, which was relieved by a binder. She then began to have pain in the left leg.

On examination two weeks after the onset of this last set of symptoms (a month after she was first seen), the patient was fibrillating with a rate of 70. The same murmurs were heard as previously described. There was marked bronchial breath-

ing over the left lower-lung field, with dullness. There was slight tenderness in the right calf and over both saphenous veins.

The temperature was normal, and the respirations were somewhat elevated. The blood pressure was 145 systolic, 90 diastolic.

Two days later, the patient complained of pain in the abdomen, without apparent localization. Extreme dyspnea appeared quite suddenly. The patient appeared pale, with cyanosis of the lips and fingertips. Death occurred several days later.

#### DIFFERENTIAL DIAGNOSIS

DR. ROBERT E. GLENDY: We can draw some immediate conclusions from this case history, I believe: the patient had rheumatic heart disease of long standing, with cardiac hypertrophy, mitral-valve and possibly aortic-valve involvement, auricular fibrillation and, for some time, considerable impairment of myocardial reserve, manifested by dyspnea on effort and later by peripheral edema, which may have been the result of peripheral vascular disease; however, toward the end of her life, she had multiple embolic manifestations, presumably from both sides of the circulation.

Although the precordial soreness, pain in the left arm and the bait thrown out in the report of the electrocardiogram tempt one to consider myocardial infarction with mural thrombus formation as a possible source of emboli, the clinical manifestations were too vague, and it is likely that the T-wave changes in the electrocardiogram were due to digitalis instead of myocardial infarction. The patient was well into the coronary age group, but I am willing to discard coronary disease as an important factor. However, an infarct involving the septum of the heart with mural thrombi on either side could conceivably account for embolic manifestations on both sides of the circulation.

It appears that until four or five weeks before the patient consulted her physician, the symptoms were those of a gradually diminishing cardiac reserve. Then she developed an aching pain in the left upper arm; constantly present, but worse on effort—presumably, effort involving the arm—and lasting four weeks, at the end of which time there was a severe exacerbation of the pain. There is no further mention of this pain, and the only clue we have regarding it is the statement that "the pulse seemed stronger in the right arm than in the left." In view of subsequent events, it is fair to assume that the symptom was due to an embolus to the left arm that impaired the circulation sufficiently to cause pain but did not endanger the nourishment of the tissues because of the free anastomotic circulation in the arm. The exacerbation of the pain was probably due to propagation

of a thrombus proximal to the embolism; such propagation often occurs. Next, the patient developed numbness and coldness in the right leg, the latter being confirmed on physical examination, and pulsations of the dorsalis pedis artery could not be felt in the right foot. Here again, the circulation to an extremity was impaired, I believe, by an embolus, but not sufficiently to necessitate or warrant any drastic measures to save the affected part. These two emboli found their way into the peripheral circulation by way of the left side of the heart, and of necessity came from either the pulmonary veins or the chambers of the heart itself. Assuming that the septal tissues were intact, the most likely source was from an auricular thrombus.

After about two weeks, the patient developed a sudden sharp pain over the left chest, with respiratory embarrassment, and in the course of time was found to have signs of consolidation in the left lower lung. I should interpret this episode as one of pulmonary infarction from an embolus. With pain in the left leg and tenderness in the right calf and over both saphenous veins, thrombophlebitis in the deep and superficial veins of the lower extremities seems a likely source of such an embolus. In the presence of any sort of septal defect, venous thrombosis in the extremities might, in fact, account for all the embolic manifestations in this patient, but I do not believe such a defect was present here.

The terminal symptoms included unlocalized abdominal pain, sudden extreme dyspnea, pallor and cyanosis. The abdominal pain may very well have been the result of the migration or propagation of a large thrombus from either extremity or from the pelvic veins. The sudden dyspnea and circulatory collapse, from which the patient died, I should interpret as due to massive pulmonary infarction from an embolus arising in the deep venous circulation.

If I am correct in my analysis of this case, post-mortem examination should reveal: rheumatic heart disease, myocardial hypertrophy, mitral stenosis and regurgitation, possibly slight aortic stenosis, evidence of mural thrombi in the left auricle, thrombophlebitis of the deep and possibly the superficial veins of the lower extremities,—with a free or propagating thrombus in the larger venous radicles,—multiple pulmonary infarcts and evidence of peripheral embolism to the right leg and left arm.

DR. PAUL D. WHITE: I should like to ask Dr. Glendy if he thinks the engorgement of the neck veins noted on first examination and the changes in T waves might be due to a dilatation of the right ventricle, not wholly from failure but perhaps

from a previous episode of pulmonary embolism.

DR. GLENDY: I think that is true. All we have to go on so far as previous pulmonary infarction is concerned is the condition of the lungs reported on the first examination and said to be essentially normal. Of course, I suppose it is possible to have pulmonary infarction of sufficient degree to produce such a picture, but it does not seem likely in view of the fact that the lungs were reported normal.

DR. WHITE: It would help to explain the electrocardiogram.

DR. GLENDY: Yes.

#### CLINICAL DIAGNOSES

Rheumatic heart disease.  
Mitral stenosis and insufficiency.  
Slight aortic stenosis.  
Auricular fibrillation.  
Coronary insufficiency?  
Embolus, right leg.  
Phlebitis.  
Pulmonary infarct.

#### DR. GLENDY'S DIAGNOSES

Rheumatic heart disease.  
Myocardial hypertrophy.  
Mitral stenosis and regurgitation.  
Slight aortic stenosis?  
Mural thrombi, left auricle.  
Thrombophlebitis, lower extremities.  
Multiple pulmonary infarcts.  
Embolism, right leg and left arm.

#### ANATOMICAL DIAGNOSES

Coronary thrombosis.  
Infarction of heart, old and recent.  
Endocarditis, chronic, rheumatic, with mitral stenosis (severe) and aortic stenosis (slight).  
Pulmonary embolism.  
Pulmonary infarction.  
Pleural effusion, left.  
Thrombosis, popliteal veins, bilateral.  
Embolism, popliteal artery, right.  
Infarct of kidney, right.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: Post-mortem examination bore out most of Dr. Glendy's predictions. It showed a little more as well. There was an old rheumatic heart disease, with a fairly severe mitral stenosis and also involvement of the aortic valve, although not enough, I should think, to be functionally significant. There was also severe coronary sclerosis, with diffuse atherosclerotic narrowing of all the branches and a fairly recent thrombosis in the right coronary artery. Consequent to

this was a focus of infarction in the posterior wall of the left ventricle, with an overlying thrombus. There was no thrombus in the auricle. The embolus was found in the right popliteal artery. Unfortunately, the left brachial artery was not examined, so that we cannot say whether there was or was not an embolus. Almost certainly, the source of the emboli was the thrombus overlying the cardiac infarct.

DR. WHITE: The thrombus in the coronary artery could not have been embolus?

DR. MALLORY: I do not believe so. It overlay an atheromatous plaque, and looked like a perfectly good thrombus of fairly recent origin. There was a small infarct in the kidney as another manifestation of embolism. Thrombophlebitis was found in the deep veins of the calf on both sides, more marked on the left than on the right. Pulmonary emboli were present. One of these had evidently occurred many days; perhaps a couple of weeks, before death and had produced a rather large single infarct of the left lower lobe. This embolus was rather firmly adherent in the branch of the pulmonary artery, and the infarct showed early signs of organization at the periphery. There had also been a shower of smaller emboli to other pulmonary vessels, particularly in the right lung, none very large, and all out in the periphery; all of them were very recent, none caused infarction, and none were adherent. That, I imagine, represents the terminal episode.

DR. WHITE: The earlier infarct might have been there prior to two weeks.

DR. MALLORY: About two weeks would be my guess on that.

DR. WHITE: After the patient was examined the first time?

DR. MALLORY: Yes; there was an episode of pleural pain at about the right time.

DR. GLENDY: What about the explanation of the phlebitis? Was there any propagation in the pelvis?

DR. MALLORY: We found nothing above the popliteal veins. One thing of a little interest was a left hydrothorax of 3500 cc.—a very large amount of pleural fluid. Usually, when unilateral hydrothorax is present, it is on the right, but in this case the right pleural cavity was dry. Small pleural effusions do occur secondary to infarction, but we have never seen a pleural effusion approaching the size of this one that we should heretofore have attributed to infarction.

DR. WHITE: Did you state the age of the myocardial infarct?

DR. MALLORY: The sections show both old scarring and fairly fresh necrosis. I cannot estimate its age with any accuracy.

**SUBSCRIPTION TERMS:** \$6.00 per year in advance, postage paid, for the United States (medical students, \$3.50 per year); Canada, \$7.04 per year, Boston funds \$5.52 per year for all foreign countries belonging to the Postal Union.

Material for early publication should be received not later than noon on Friday.

The Journal does not hold itself responsible for statements made by any contributor.

Communications should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston, Massachusetts.

## PROCUREMENT AND ASSIGNMENT SERVICE

The enrollment forms and the questionnaires for the Procurement and Assignment Service have been or are about to be forwarded to every registered physician in the United States. The need for medical officers in the armed services is acute, and at the same time medical services to other governmental agencies, industry and civilian communities must be provided or maintained. Hence, all physicians, regardless of age, sex, race, physical condition, citizenship or employment, and regardless of any enrollment forms or questionnaires that have previously been made out, should carefully fill out these forms and **IMMEDIATELY** return them in the envelopes that are enclosed, which require no postage. Only with

the information that will be obtained from these forms by the National Roster of Scientific and Specialized Personnel, which will be made available to the Procurement and Assignment Service, can the latter intelligently and expeditely perform its functions, which are so vital to the war effort.

## "HOLD FAST THAT WHICH IS GOOD"

A EUROPE in ruins laments the wanton destruction of the physical monuments of its civilization. Cathedrals are reduced to rubble; art galleries are destroyed, and their treasures of painting and sculpture burned, broken or ravished; schools, hospitals, reservoirs, railways, all the implements of civilization are scattered upon the blasted earth, whose peoples succor their wounded and lament their dead. And all because a paranoiac person with a messianic megalomania has indoctrinated a part of a great nation with a passion for the satisfaction, by ruthless force, of spurious grievances, and has cowed the rest into subservient support of his infamous ambitions.

Libraries have not escaped this holocaust. Louvain, barely rebuilt since the *furor Teutonicus* razed it, has again been leveled. The Royal College of Surgeons is in ruins—its priceless literary treasures, its collections prepared by the very hands of John Hunter, its medical memorabilia blown to bits. The University of Paris has been robbed for the enrichment of the seats of spurious learning of the self-styled Nordic superman, whose servile sycophantic scholars pervert and falsify the accepted facts of history and science to give plausibility to his monstrous ideology.

We in America, so remote geographically from the lair of this Caliban of civilization on the East and from his infamous imitators to the West, cannot believe that our homes and treasure houses are in real danger of physical destruction. Perhaps we are right; or perhaps we have learned nothing from Pearl Harbor and Bataan. Be that as it may, there are other dangers, insidious but fatal. A library may be demolished by a bomb, or it may suffer slow and deadly decay from neglect. We are bringing all our resources—mental, physical and

financial — to the winning of a free way of life for the peoples of the earth. It would be folly to lose through indifference the fruits of years of patient effort. Such fruits are perishable; they cannot be left unwatered for the duration of the national emergency with the expectation that they will be found sound and nourishing afterward.

Such an institution is the Boston Medical Library, whose present situation and prospects are described in the annual report of its president elsewhere in this issue of the *Journal*. It deserves and should receive, in some form or other, the support of every reputable physician in Boston — or, rather, in New England. Those who are fellows should not withdraw unless forced to by dire necessity; those who are not should seek fellowship. All should encourage it by entering its house to enjoy its privileges and by spreading abroad its good report. The purpose of its custodians has not changed since Dr. Chadwick, some sixty-four years ago, in the third year of its existence, wrote the first request for funds: "With this record of past achievements, the Association now appeals for aid to meet its present wants, and to provide for its immediate entrance into a wider sphere of prosperity and usefulness."

---

## TYPHOID CARRIERS

THE day is past when typhoid fever is being spread in large epidemics by water and milk. Safeguards now thrown around such supplies eliminate the possibility of large epidemics, and small ones are becoming exceedingly rare. Although, since 1915, the disease has decreased in Massachusetts from the level of over 2000 cases a year to less than 100 a year, there is no expectation that it can be completely eliminated, because numerous sources of infection are still present.

It is a well-established fact that more than 3 per cent of the persons who contract typhoid fever continue to harbor typhoid bacilli during the remainder of their lives, usually in the gallbladder but sometimes in other foci. In the years when the prevalence of typhoid fever was high, facilities to detect convalescent carriers by proper laboratory

supervision of recovered cases were not available. Consequently, many of those who had the disease in the past now harbor virulent typhoid bacilli in their intestinal tracts and many of the typhoid cases of the present day are due to contacts with such persons. From time to time, estimates have been hazarded regarding the number of typhoid carriers now present in Massachusetts. These estimates have varied within considerable limits, but there are probably at least 1500 such carriers in the State today. Only one tenth of these cases are on the records of the Department of Public Health, and most of these were discovered in the investigation of reported cases.

It is therefore not surprising that occasional incidents such as those described in a paper in this issue of the *Journal* occur from time to time. Most physicians are familiar with the fact that the typhoid bacillus is one of the etiologic agents of cholecystitis. Nevertheless, when a disease is at as low a prevalence as typhoid fever is today, this fact is easily forgotten. In such cases, failure to observe strict precautions may result in the infection of a nurse or a house officer.

From the much publicized story of Typhoid Mary,<sup>1</sup> it is the usual impression that typhoid carriers are very dangerous, causing numerous cases of the disease. Fortunately, in an area where public sanitation and personal hygiene are at as high a level as in New England, it is unusual for such persons to cause cases. Some have gone as long as thirty and forty years without apparently having ever given rise to a single case. The fact that 1500 carriers in Massachusetts are producing only about 75 cases of typhoid fever a year bears out this statement.

So long as typhoid fever continues at its present low rate of prevalence, current cases will produce only a few carriers each year. Furthermore, most of the carriers in the State are persons who had their typhoid fever many years ago and are, consequently, dying off at a high rate. It is therefore to be expected that the disease will drop to even lower levels than those prevailing at present, in

spite of the migration of occasional carriers into the State from areas of higher prevalence.

Physicians treating cases of cholecystitis should make careful inquiry concerning previous typhoid fever. When a past history is elicited, careful laboratory studies should be made to exclude the carrier state. Such preventive measures will dis-close additional carriers and eliminate the chance of infecting contacts in the home and in the hospital.

Recently, the investigation of a case of typhoid fever in a child disclosed the grandmother as the source of infection.<sup>2</sup> The child became ill a few months after the grandmother had been in a hospital where she was under treatment for cholecystitis and cholelithiasis. A careful history at the time of this admission would have disclosed an attack of typhoid fever many years before. Laboratory study would have revealed the carrier condition and prevented a possible death from typhoid fever.

#### MEDICAL EPONYM

##### OPPLER-BOAS BACILLI

These were described by Bruno Oppler, a Berlin gastroenterologist who had been an assistant of Ismar Boas (1858) in the Polyclinic, in the *Deutsche medizinische Wochenschrift* (21:73-75, 1905). The title of the article containing the description is "Zur Kenntniss des Mageninhalts beim Carcinoma ventriculi [On the Recognition of Stomach Contents in Carcinoma Ventriculi]." A portion of the translation follows:

Uncommon as it is to find an entire absence of micro-organisms in the microscopic examination of the stomach contents, it is even rarer that they dominate the field of vision at the expense of all other elements. Leaving yeast and sarcinas for the present out of consideration, up to the present time I have practically found this only in carcinoma. Here there is an apparently quite definite variety of rather slender bacilli, which are grouped in long threads and zigzag lines that so dominate the field that they fill the spaces between the other elements (food particles and so forth) and at times are matted together in thick bundles. Presumably, this is a saprophyte. . . . This luxuriant bacterial growth is particularly seen in carcinomas when the stomach contents show, together with the absence of free hydrochloric acid, the signs of very much di-

minished motility; that is, in those cases in which lactic acid is produced. I have sought for them in vain in the stagnant stomach contents of benign pyloric stenosis or atonic gastrectasis, although, to be sure, these usually contain abundant free hydrochloric acid.

##### CASE HISTORY: TOXEMIC PREGNANCY FOLLOWED BY UNSUCCESSFUL OPERATIVE DELIVERY AND DEATH

A thirty-four-year-old primipara was sent into the hospital a week before expected labor because of a blood pressure of 130 systolic, 80 diastolic, and a large trace of albumin. She had not been seen during her pregnancy until this date. The past history was essentially irrelevant. The heart and lungs were normal, the uterus was enlarged to a size compatible with term, and the fetal heart was audible. On admission the patient was put to bed and treated medically for this mild toxemia. The blood pressure is said not to have risen any higher, although albuminuria was constant. There was a good deal of swelling in both legs. Six days after entry, labor started spontaneously, and at the end of twelve hours the cervix is said to have been fully dilated. Because of lack of progress, a forceps delivery was attempted but was unsuccessful. Another operator attempted version, which was likewise unsuccessful. By this time, the patient's general condition was poor, and the pulse was rapid, although there is no mention of external bleeding. A consultant was called eight or ten hours later, but the patient died undelivered before his arrival.

*Comment.* This whole case represents atrocious obstetrics. Only the hospitalization and rest in bed for a week before the onset of spontaneous labor are to be commended. It is perfectly possible that the pelvis was not adequate for this particular baby, or that the attempt at forceps delivery failed solely because of the lack of skill on the part of the operator. Had the patient been intelligently observed after the forceps delivery had proved unsuccessful, it would not have been too late to perform an extraperitoneal cesarean section. The unsuccessful attempt at version emphasizes the inadequacy of the medical care. It is possible that in the attempt at version the uterus was ruptured and that death, which occurred several hours after this operation, was due to continued bleeding into the peritoneal cavity.

Such obstetric mismanagement would not occur in any hospital where adequate supervision is routine, and the death was, of course, avoidable.

## WAR ACTIVITIES

### CIVILIAN DEFENSE

#### PLAN TO ESTABLISH BLOOD BANKS

Hospitals in communities exposed to war hazards may receive assistance in the establishment of a blood and plasma bank through funds available to the United States Public Health Service, which will be administered by it through the Medical Division of the United States Office of Civilian Defense. In addition to providing whole blood or liquid plasma for the current needs of hospitals, these blood banks, as well as others already in operation, are to accumulate a reserve supply of plasma for civilian casualties caused by enemy action. Technical and bacteriologic safeguards are to be observed, as recommended by the Subcommittee on Blood Substitutes, Division of Medical Sciences, National Research Council. At the request of the Office of Civilian Defense, a technical handbook on blood and plasma banks has been prepared by this committee, which will be distributed by the Office of Civilian Defense to hospitals.

Following the advice of the committee of the National Research Council, financial and technical assistance will be provided to only three hundred hospitals of 200 or more beds approved by the American College of Surgeons and the Hospital Register of the American Medical Association. These hospitals will agree to maintain required technical standards and to accumulate a surplus of liquid or frozen plasma amounting to one unit per bed within three months. Grants will be made only for the purchase of essential equipment if obtainable locally and for sufficient technical assistance to initiate the project. Hospitals will thereafter be expected to continue to maintain the blood and plasma bank to meet their daily needs as well as the plasma reserve for civilian casualties.

Technical guidance has also been made available through the appointment of Dr. John B. Alsever, of Syracuse, New York, by Surgeon General Parran, of the United States Public Health Service, and his assignment to the Medical Division of the Office of Civilian Defense as technical director of its blood and plasma service. Dr. Alsever will be assisted by regional technical consultants in various parts of the country, whose consulting services will be made available to hospitals in their area.

As a further safeguard for the civilian population, the United States Public Health Service is providing for the production of 50,000 units of dried plasma or human albumin in laboratories approved for the manufacture of biological products by the National Institute of Health. The American Red Cross has agreed to collect the blood for this purpose without interference with its blood-collecting services for the armed forces. This second reserve of dried plasma will be distributed to Office of Civilian Defense depots located in various parts of the country. It will be made available by the Medical Division of the Office of Civilian Defense to stricken communities for their casualties whenever their own local stores of liquid or frozen plasma are in danger of being depleted.

Regional medical officers of the Office of Civilian Defense, who are appointed in the Public Health Service, will be the regional representatives of both agencies for this program. State chiefs of Emergency Medical Service or their deputies may also be appointed consultants or commissioned in the Public Health Service, so that they may act as state representatives for the two agencies in the organization of emergency hospital facilities and the reimbursement of hospitals for the care of civilian casualties. In the more populous coastal states, a full-time state hospital officer may be needed, who will also be eligible for appointment in the Public Health Service.

## MISCELLANY

### NOTES

The sixty-seventh annual reunion and banquet of the alumni of Boston University School of Medicine was held on Thursday, April 23, at the University Club, Boston. Dean Bennett F. A. Avery stated that seventeen members of the staff of the medical school are on active duty with the armed forces and that another is doing research work at the request of the War Department. Dr. Henry M. Pollock, superintendent of the Massachusetts Memorial Hospitals, spoke on the completion of the new Evans Memorial Medical and Research Building, to be opened on May 12. The following officers were elected: Dr. John M. Wilcox, '18, of Woburn, president; Dr. Clifton B. Leech, '19, of Providence, Rhode Island, first vice-president; Dr. Eleanor B. Ferguson, '20, of Boston, second vice-president; Dr. Frank E. Barton, '24, of Boston, secretary; Dr. Kenneth Christophe, '38, of Needham, treasurer; and Dr. Milo C. Greene, '16, of Lynn and Dr. James E. Vance, '23, of Natick, directors for two years.

Boston University School of Medicine has recently received an outright gift of \$10,000 from the W. K. Kellogg Foundation, Battle Creek, Michigan, to be used for student scholarships and loans, with the purpose of assisting in the training of men for military service. The money will be available on July 1, the beginning of the next fiscal year.

## CORRESPONDENCE

### PHYSICIANS FOR THE VETERANS ADMINISTRATION

*To the Editor:* The source of supply of qualified physicians for service with the Veterans Administration has, during the past several months, sustained serious inroads by the needs of the armed forces.

The Procurement and Assignment Service, established by the President, has released to all physicians in the United States a questionnaire to determine the availability of physicians for service with the Government, either in the armed forces or in the civil services. In filling out these questionnaires, physicians may designate their preference for assignment during the present war.

Physicians enter the Medical and Hospital Service of the Veterans Administration in the grade of associate physician, at approximately the same pay as a first lieutenant in the Medical Corps of the United States Army. The volume and variety of the medical activities of the Veterans Administration are approached by few if any other organizations. Abundant clinical material is afforded in all fields of medicine and surgery, except obstetrics and pediatrics. Furthermore, there is ample opportunity for research for those who are interested.

Physicians interested in receiving an appointment should write to the United States Civil Service Commission or to Major Sam F. Seeley, Procurement and Assignment Service, 601 Pennsylvania Avenue, N.W., Washington, D. C., and should also express their preference when completing the questionnaire.

WINTHROP ADAMS, M.D., *Manager*

Veterans Administration  
Bedford, Massachusetts

### TYPHOID FEVER IN HOSPITAL PERSONNEL

*To the Editor:* Because of the occurrence of typhoid fever in hospital personnel, the attached letter was sent to the superintendents of all hospitals and related institutions

in Massachusetts. I suggest that the letter be printed in the columns of the *Journal* for the information of the physicians of the State

PAUL J. JAKMAHL, M.D.  
Commissioner of Public Health

State House  
Boston

#### TO HOSPITAL SUPERINTENDENTS

Cholecystitis may be of typhoid origin. Hospital personnel in charge of gall bladder cases on both medical and surgical wards should constantly keep this point in mind. Recently, a physician in one Boston hospital and a nurse in another contracted typhoid fever because this fact was not taken into consideration\*. The first case was that of a surgical house officer who developed the disease as a result of direct contact with a previously unrecognized typhoid carrier who had just undergone cholecystectomy. The second case was a student nurse who contracted the disease while taking care of a missed case of typhoid fever admitted to the surgical ward as a case of acute cholecystitis.

Exposures to such unrecognized cases of cholecystitis of typhoid origin constitute a real risk to hospital personnel. To avoid such infections it has been recommended that all cases of chronic cholecystitis with a past history of typhoid fever be placed on typhoid precautions until laboratory studies exclude the carrier state. In addition, extreme care should be exercised by those handling dressings and discharges of all other gall bladder cases.

On several occasions in the past, this department has called to the attention of hospital superintendents the occurrence of secondary infection among persons caring for typhoid fever cases before the disease had been definitely diagnosed. It is, therefore, evident that many hospital employees have not been sufficiently protected against typhoid fever by vaccination. Physicians, nurses, laboratory workers and ward attendants are among those requiring antityphoid inoculations.

In addition to the primary series of three subcutaneous inoculations, a single stimulating dose should be administered once a year in order to maintain a sufficiently high level of immunity. This stimulating dose may consist of either 0.5 cc. of the vaccine subcutaneously or 0.1 cc. intradermally.

In the light of present world conditions, it is to be expected that increasingly great responsibilities may come to fall on professional personnel of hospitals. It is important that every possible safeguard be provided for such workers. The proper management of persons with gall bladder disease and those ill with fever of undetermined origin together with antityphoid inoculation of personnel, will reduce considerably the risk of typhoid fever.

PAUL J. JAKMAHL, M.D.  
Commissioner of Public Health

Note: Cholecystitis of typhoid origin (typhoid carrier) is a reportable disease.

\*There were cases as reported and commented on editorially in this issue of the Journal.—Ed.

#### REPORT OF MEETING

##### BOSTON ORTHOPEDIC CLUB

A regular meeting of the Boston Orthopedic Club was held at the Boston Medical Library on December 15, with Dr. Otto J. Hermann presiding. The speaker of the

evening was Dr. John Scudder, of New York City, who discussed 'Shock'.

Studies on the ionic changes during this condition, particularly in regard to potassium, originated in the work of the botanist, Osterhout, and have been carried on by Dr. Scudder after the manner of Dr. James L. Gamble. Allusion was made to the increased action current by an elevation of the potassium content of a system and its return to normal when sodium is introduced. The close analogy of sea water, plasma and interstitial fluid brought out by Dr. Gamble was contrasted to the great difference in cellular fluid. The deleterious effect of the potassium ion on the electrocardiogram of the cat and the saving effect of sodium or adrenocortical extract were pointed out.

Several varieties of experimental shock were shown to have the common factor of a change in the potassium ion content. Noxious stimuli are known to increase shock, which is a principle behind the deflation of intestinal obstruction. Distention of a balloon in the intestinal tract of a cat not only increases the specific gravity of the blood but also causes an elevation of the potassium content. These values return to normal only if the distention is relieved in less than thirty-six hours, but not if the condition persists over forty-eight hours. This, of course, is an important consideration in the treatment of shock. Esophageal obstruction is as fatal in the cat as that at the duodenum, with an elevation of the specific gravity of the blood thirty-six hours before any ionic changes occur. Similar electrolyte changes occur in acute pancreatitis and hemorrhage, but are measurable only late in the syndrome. The protein values change but little. The terminal outpouring of the potassium ion from the tissues occurs after all other materials have been exhausted. In experimental shock produced by trauma, there is an elevation of serum potassium that is relieved by the administration of sodium. Therefore, one variable of all types of shock appears to be an alteration of all the body fluids as well as plasma, such as the cerebrospinal, pericardial, peritoneal, lymph and tissue fluids.

Cases of shock of various sorts in human beings were cited. In a case of ruptured kidney, an early and rapid rise of serum potassium only gradually assumed normal levels. Early operations in such cases are contraindicated, therefore, and should be postponed until normal kidney function has been restored. In a case of an untreated burn, there was absorption of material from cellular breakdown causing an elevation of the potassium ion, with gradual resumption of normal levels in this strong patient. But such a recovery might not occur in all untreated patients. On the basis of these findings, dehydration therapy for severe head injuries is considered injudicious.

Dr. Scudder emphasized the significance of the electrolyte changes in shock, but pointed out that evidences of hemoconcentration are so far the earliest measurable signs of incipient or early shock. A comparison of venous and capillary blood affords a simple rough method for evaluating this factor, and Dr. Walter B. Cannon showed during World War I that values of 8,000,000 and 5,000,000 red blood cells per cubic millimeter in the capillary and the venous blood, respectively, indicate that irreversible changes have already occurred and that death is inescapable. In determining the degree of hemoconcentration as an indication of shock, Dr. Scudder suggests the use of four determinations: the hematocrit, the specific gravity of whole blood, the specific gravity of plasma and the plasma protein. Any of these alone may be misleading. Anemia may offset dehydration in the hematocrit reading, for example.

The type of therapy should be based on these findings. If hemoconcentration results in an elevation of plasma protein, it is permissible to use parenteral saline infusions prior to transfusion. On the whole, blood is the best therapeutic agent in the treatment of most cases of shock. If blood banks are used, it is essential to withdraw the blood under carbon dioxide to keep the ionic elements in their proper proportions. The use of adrenocortical extracts, as suggested first in World War I, fell into disuse for several years, but has recently been shown in histologic and clinical studies to be of definite benefit in many cases of shock. It has therefore become a useful adjunct to the armamentarium of shock therapy.

As a result of studies on electrophoretic patterns of various blood substitutes, it has been concluded that cellophane bags are not adequate for the storage of plasma. Likewise, frozen plasma has been found more stable than the liquid form. Cohn's albumin is very pure and shows definite possibilities as a blood substitute, but certain caution should be exercised in its use. It calls potassium into the blood stream and builds up the circulating blood volume by withdrawing the intracellular fluids. There is also apt to result an elevation of pulse pressure without a true rise of blood pressure. There is still no complete substitute for blood and sodium chloride in adequate amounts and appropriate proportions. In shock from hemorrhage, physiologic saline solution and adrenocortical extract should be administered first. Then, albumin or blood should be given. If blood banks are to be used, the depots must be very large, as evidenced by the giving of 14 liters of blood in thirty days to a patient with burns.

The discussion was opened by Dr. Walter B. Cannon, who compared some of the simpler early concepts of the mechanism of shock with those of the more recent observers. He asked whether isotonic albumin should be used rather than hypertonic, and also whether the potassium freed during the early stages of shock was enough to cause a fall of blood pressure. It was stated that some observers have not had good results with adrenocortical extract, whereas Katz, in Chicago, believes that desoxycorticosterone acetate may be helpful if given prophylactically. The question was raised concerning the advisability of using plasma alone in burns.

The discussion was continued by Dr. Kenneth Coonse, who emphasized the value of the early diagnosis and proper treatment of shock and minimized the question of potassium ion as a cause or effect of the phenomenon. It was pointed out that the histologic changes observed in the adrenal glands are also demonstrable in other organs and probably are not specific. Other organic extracts might therefore help at the appropriate time, but nothing will be of avail beyond a certain point.

Dr. J. E. Dunphy stressed the need for controlled fluid therapy rather than mere fluids. Potassium is probably not all important or even of primary advantage. Capillary permeability may be caused by the absorption of toxins from sepsis. The prime factor apparently is a discrepancy between the existing vascular bed and the circulating blood volume, and this may be brought about by a number of causes. An increase of the vascular bed may result from nervous impulses such as those following a high spinal anesthesia. Toxins may cause direct injury to the vascular system, and this seems to cause changes in the specific gravity of the blood and plasma protein secondary to the fall of blood pressure. Hematogenic shock, as seen in blood loss, does have initial changes similar to those de-

scribed by Dr. Scudder. Adrenocortical extract has a rational basis and deserves a place in shock treatment, but should not be accepted as a cure-all.

In conclusion, Dr. Scudder emphasized the facts that adrenocortical extract was only one phase of the subject and that its use is absolutely contraindicated in shock from sepsis. One practical observation is that a continued increase of hemoconcentration in the presence of saline infusions indicates the approach of irreversible shock.

## BOOK REVIEWS

*The Autonomic Nervous System: Anatomy, physiology and surgical application.* By James C. White, M.D., and Reginald H. Smithwick, M.D. Second edition. 8°, cloth, 469 pp., with 92 illustrations and 19 tables. New York: The Macmillan Company, 1941. \$6.75.

The first edition of this book, written in 1935 by Dr. White alone, was well received and proved to be a valuable contribution to current medical literature. In six years, much has been added to knowledge of the autonomic nervous system by anatomists, particularly Ranson and Clark, by physiologists, such as Cannon and Fulton, and by surgeons, the two authors of this new edition being important contributors themselves. The book, nearly completely rewritten and vastly improved in its new form, is a fundamental text, invaluable to surgeon, neurologist, cardiologist and many others. The period between editions has given the authors time to revise the old and add the new; the publishers have fully co-operated, and physicians are presented with a complete, up-to-date treatise. The volume, like the first edition, is highly recommended.

*Society and Medical Progress.* By Bernhard J. Stern. 8°, cloth, 264 pp. Princeton, N. J.: Princeton University Press, 1941. \$3.00.

This book was long overdue, and now that it has arrived, students of medical history and sociology will find it a valuable tool in the consideration of problems that directly concern medicine and society. The author, a social scientist of note, brings to the presentation of his material a broad background of intellectual knowledge, a keen understanding of medical problems and a penetrating analysis of the social factors that mold, and in turn are molded by, the advance of medicine. The reader is offered a stimulating review of the steps taken by medicine from its infancy to its present status. The tone of the narrative is heightened by a good account of the role of the medical schools and the development of the modern hospital. The subsequent chapters on urbanization, income and health, conquest of famine, medical advances and social progress and resistances to medical changes give a most graphic picture of the inevitably close relation that now exists between medicine and society.

One is a little disappointed at not finding reference to Zabdiel Boylston or W. T. G. Morton. Furthermore, to find on page 182 that the Warburton anatomical act of 1832 is referred to as the first of a series of laws in this connection is to overlook the fact that Massachusetts passed the first anatomical act in 1831. These points, however, are indeed minor.

A feature worthy of special note is the excellent bibliography for each chapter that is found at the end of the book. The reviewer is convinced that a book such as this one should be placed in the hands of all readers.

## A STATISTICAL STUDY OF SIX HUNDRED AND SEVENTY-ONE CASES OF APPENDICEAL PERITONITIS\* (Concluded)

HENRY H. FAXON, M.D.,<sup>†</sup> AND HORATIO ROGERS, M.D.<sup>‡</sup>

BOSTON

### PART II. TWO HUNDRED AND TWENTY-SEVEN CASES WITH PALPABLE MASS ON ADMISSION TO THE HOSPITAL

IN the previous section, dealing with appendiceal peritonitis unassociated with a demonstrable mass, we pointed out the fallacy of attempting a classification on a purely pathological basis, and again we should like to state that it is only by implication or an unjustifiable exhaustive exploration that such a distinction can be made.

The presence of a palpable mass is of major importance in determining the course of treatment and in influencing the prognosis. It is indisputable evidence of a variable degree of localization of the inflammatory process and hence serves to establish a very different clinical entity from those cases in which the possibility of the formation of such a mass is still problematical, and in which it is unjustifiable to assume that such localization will of necessity ever take place.

We have used the term "mass" advisedly throughout this study because a palpable inflammatory tumor is not necessarily synonymous with an "abscess" within the usual meaning of the word. Much confusion has arisen because of the ill-defined usage of the term "appendiceal abscess," which has been employed in certain cases to describe an extensive area of inflammatory fixation about a gangrenous appendix, and in others, a small collection of pus with a negligible number of surrounding adhesions. The term "mass" refers to a tumor of inflammatory origin, of sufficient size

to be demonstrated by palpation, only secondary significance is attached to the fact that such a mass might be constituted in part of a variable amount of frank pus.

The palpation of a mass in the course of physical examination was possible in 154, or 68 per cent, of these 227 cases. In 32, or 14 per cent, the mass was first noted after the administration of an anesthetic, but before the incision had been made. In 32, or 14 per cent, no mass was noted prior to opening of the peritoneal cavity, but at exploration an inflammatory tumor was found that, from its size and location, should presumably have been detected. In the remaining 9 (4 per cent) cases, not only was the mass not felt preoperatively, but even with the abdomen opened, it seemed unreasonable to suppose from its relative inaccessibility to external or rectal palpation that it could have been discovered prior to operation.

From this it can be seen that in 82 per cent of these cases the preoperative decision concerning the type of treatment the patient was to receive should have taken into consideration the fact that a mass was present as unmistakable evidence that localization of the infectious process had occurred. It is clear that in many cases the surgeon failed to palpate the abdomen after relaxation had been secured, and before making his incision, and thus embarked on a course of treatment founded on an erroneous conception of the lesion present. It is our opinion that in cases in which a definite mass is first detected after the patient is anesthetized, the question of proceeding with the operation at that time in the light of this new finding should be re-evaluated, for the danger of premature disrup-

\* Inroduction and Part I of this paper appeared in the April 30 issue of the *Journal*.  
Read by title at the annual meeting of the New England Surgical Society, Harvard New Hampshire, September 5 and 6, 1941.

‡ Chief of surgery, Harvard Medical School, associate visiting surgeon, Massachusetts General Hospital.

tion of a definite but inadequately established walling-off process may far outweigh the danger of a second anesthetic.

In a study that professes to be concerned with the clinical problems presented by patients suffering from appendicitis with an associated mass, it may seem illogical to include the 18 per cent of cases in which the true nature of the lesion was not appreciated before the peritoneal cavity was opened. We believe that the inclusion of these cases is not inconsistent with our conception that the clinical problem of appendiceal peritonitis with mass formation is fundamentally different from that in which no such walling off has taken place, and that these cases differ only in the stage of investigation at which the true status of the disease was appreciated.

The number of patients with appendiceal peritonitis and a mass who were admitted to the hospital annually from 1929 to 1940 has changed but little, and the proportion considered "very ill" on admission has remained relatively constant (Table 1). The annual number of all pa-

\*It should be noted that this tabulation covers only two years instead of the three-year tabulation of the subsequent periods.

tients admitted to the Massachusetts General Hospital with a diagnosis of acute appendicitis has remained essentially the same. Since there has been a yearly constancy in the number of patients with appendiceal peritonitis in any form, it appears that the incidence of cases that have been permitted to progress to perforation before being referred to the hospital has shown no definite tendency to decrease.

The well-recognized fact that there is a higher incidence of uncomplicated appendicitis in males than in females was likewise true in the cases of appendiceal peritonitis with an associated mass. Almost two thirds (64 per cent) of these cases occurred in males, and this figure so closely approximates the sex ratio (63 per cent males) in our study of cases without palpable mass that one may infer that if acute appendicitis goes on to peritonitis, the sex of the patient is no guide to whether or not clinically demonstrable localization will take

place. The mortality in this series was strikingly higher in males (9.0 per cent) than in females (3.7 per cent), whereas the reverse was true in the cases in which no mass was present.

The well-recognized higher mortality rate in the extremes of life in appendicitis of all types is seen to be especially striking when only patients with appendiceal peritonitis and palpable mass formation are considered (Table 2). Although nearly

half (46 per cent) these cases occurred between the ages of fifteen and fifty years, there was but a single death in this group, whereas in patients under fifteen there was a mortality of 9.6 per cent, and over the age of fifty it reached 16 per cent.

PROGNOSTIC SIGNIFICANCE OF HISTORY

Duration of Illness Before Operation

Operation carried out promptly after the onset of acute appendicitis is attended with a rapid recovery of the patient and a negligible mortality. When symptoms of the disease have been present for over twenty-four hours, the inflammation may either subside spontaneously or progress to involve the peritoneal cavity, and there are no infallible criteria for judging which of these eventualities will take place. The duration of the disease as a factor in the clinical prognosis is of greatest consequence during this indeterminate stage, when the exact nature of the lesion present is largely a matter of conjecture. However, the presence of a mass in the region of the appendix is indisputable evidence of at least a partially successful localization of the inflammation to that area, and the value of our figures regarding the duration of the disease in this series of cases consists largely in providing data from which one can decide when in the course of the condition such a mass can surgically be approached most safely. In certain cases, especially in the very young and the elderly patients, a brief history was suggestive of inaccuracies concerning the recorded time interval of the disease, for a demonstrable inflammatory mass rarely becomes established within forty-eight hours.

To illustrate a significant number of cases for each comparative period, the figures shown in Table 3 have been tabulated at intervals of forty-eight hours. It is apparent, from our experience

in 56 cases, that operation for appendicitis with an associated mass within the first four days of the disease is attended with a low mortality (3.1 per cent). This is in striking contrast to our findings of a 12.5 per cent mortality in patients with ruptured appendix without mass formation operated on within this same period, and emphasizes more dramatically than any of our other comparative figures the fundamental clinical difference between these two groups.

During this relatively early stage of the disease, the mass usually consisted of thickened omentum draped about the appendix, with little or no frank pus. This effective localization of the process, in a form that did not predispose to the spread of infection at the time of operation and made possible an unerring approach through the most favorable incision, provided the chief factor in the low mortality of this group.

In the forty-eight-hour period of the fifth and sixth days of the disease, there was an abrupt and startling rise in the death rate—to 17.4 per cent. From the sixth to the twelfth day of the disease, there was a definite but not unbroken trend to-

this group of patients, and although the number is small, it suggests that the occurrence of chills during the onset of acute appendicitis that goes on to form an inflammatory mass has little prognostic significance. Furthermore, a comparison of this with our other series of cases, in which the incidence of chills was essentially the same (9 per cent), leads us to believe that the occurrence of chills preoperatively is of essentially no help in determining the likelihood that the inflammatory process will extend, in contrast with its manifestation of the signs of localization.

In 1 case, in which incision and drainage without appendectomy were carried out on the twelfth day of the disease, the patient suffered chills postoperatively. The patient ran a septic course following operation and finally died, sixty-two days after drainage, of multiple liver abscesses and pyelophlebitis, confirmed by autopsy.

### Previous Attacks

One quarter (26 per cent) of the patients gave a history of one or more previous attacks, with a mortality somewhat higher for this group (8.3 per cent) than for the cases in which there was no note of an earlier attack (5.9 per cent). It would be misleading to try to draw conclusions from this relatively small difference in mortality rates, but it is of some interest that in the cases of appendiceal peritonitis without mass the apparent influence of previous attacks was favorable rather than unfavorable and that the incidence of cases in which a history of such attacks was recorded was definitely higher (40 per cent).

### Other Factors

In the first series of cases, we showed that when appendiceal peritonitis occurred and no subsequent mass developed, 25 per cent of the histories revealed a sudden episode of increased pain that was interpreted as marking the time of perforation and was of helpful prognostic significance. Only 15 per cent of the cases with a mass, however, gave any clue to when perforation might have taken place, and this fact, when available, was primarily of academic interest, for in all these cases, by the time the patient reached the hospital, localization was an accomplished fact.

A study of the patient's bowel habits immediately preceding and following the onset of symptoms did not bring out any trend of diagnostic or prognostic value. In 22 per cent of the histories, there was some definite note of cathartics, and in these cases the mortality rate (10 per cent) was twice that of the remaining cases (5.6 per cent), in which either no laxatives were mentioned or the specific avoidance of their use was so stated.

TABLE 3. Incidence and Mortality According to Duration of Disease before Operation.

Average .....				6.7	

\*Four nonfatal cases and 1 fatal case were treated without operation.

ward a lower mortality rate, and after this period the mortality reached essentially the same figure (3.2 per cent) that had obtained in the first four days of the disease.

It is therefore apparent that when a mass is present, operation done on or before the fourth or after the twelfth day is a relatively safe procedure, with but a 3 per cent mortality. Surgery carried out on the fifth, sixth or seventh day of the illness, however, is especially hazardous, accounting for nearly half (7) the deaths, although only one fifth (21 per cent) of the patients were operated on at that time.

### Chills

In 18, or 8 per cent, of the cases, there was a definite history of chills during the preoperative course of the disease. There was no mortality in

# PROGNOSTIC SIGNIFICANCE OF PHYSICAL EXAMINATION

## Degree of Illness

It has been routine in our hospital records to enter on the physical sheet the examiner's impression of whether the patient was "very ill," "moderately ill" or "not ill." The distinction between the last two groups was so poorly defined in many cases that the patients were grouped together under the single heading of "not very ill." This note is based primarily on the surgeon's intuitive evaluation of the patient's appearance, and it is interesting that in these cases, as well as in those without mass formation, it is the most significant of all the preoperative data.

Table 1 shows that 14 per cent of the patients were very ill on admission, with a mortality rate nearly four times as high (19 per cent) as that for those who were not considered very ill (5 per cent). Well over a third (42 per cent) of the very ill survivors ran stormy convalescences, as contrasted with only one quarter (25 per cent) of the remaining patients. Taken in conjunction with our first series, it is seen that very ill patients were over twice as common (32 per cent) and showed nearly twice the mortality rate (34 per cent) when no mass was present as when a mass existed.

The incidence of very ill children fifteen years or under (25 per cent) was over twice as great as that for patients between the ages of fifteen and fifty (8 per cent), or over that age (12 per cent). This explains in part the high mortality in children, but cannot be advanced as the cause of the even higher rate found in the elderly group.

## Stage of Treatment at Which Mass was Detected

In the 68 per cent of the cases in which the presence of the mass was appreciated before operation and before an anesthetic was administered, the mortality (Table 4) was less than half (5 per cent)

TABLE 4. Incidence and Mortality on Basis of When Mass Was Detected.

MASS DETECTED	NO OF CASES	INCIDENCE %	NO OF DEATHS	MORTALITY %
On physical examination	154	68	7	5
Under anesthesia	32	14	4	13
At operation (should have been felt preoperatively)	31	14	4	13
At operation (could not have been felt preoperatively)	10	4	1	10
Totals	227		16	

that found in the remaining cases (12 per cent). Undoubtedly, the fact that it was possible to palpate without anesthesia an inflammatory tumor in 154 cases means that in this group the process had become better established or was more favorably

located in the right gutter than in the other cases. One would expect the preoperative history to be longer when a mass could be made out on physical examination, and this was borne out by the facts.

In the 14 per cent of the cases in which a mass was first felt under anesthesia, the mortality was 13 per cent. In no case did a surgeon who discovered a mass on the operating table desist from proceeding with surgery, although such a policy has been successfully adopted subsequent to the period covered in this report.

In all the remaining cases (18 per cent), in which the mass was discovered only after the peritoneal cavity had been opened, appendectomy or drainage was carried out at that time with a mortality of 12 per cent. In only 2 such cases did the operator close his original incision and drain the area through a lateral approach; these patients made an uneventful recovery, and we are confident that many of the others would have fared better had similar mental flexibility been shown more frequently.

So far as could be determined from the records, the majority of the masses were located laterally, and detection of the mass and ease of drainage without contamination of the general peritoneal cavity were naturally greatly facilitated.

## Absent Peristalsis

The fact that the infection had progressed to the point where localization was demonstrable as an inflammatory mass suggests that the greater part of the general peritoneal cavity was free of active infection at the time of admission. This relative freedom from widespread infection is confirmed by the fact that in 122 cases peristalsis was stated as being normal in 83 per cent, as contrasted with 26 per cent of the cases without a mass. Whereas, in the latter cases, absence of peristalsis was attended with a mortality of 28 per cent and provided one of the most significant and unfavorable physical signs, in this series of cases it was of little prognostic advantage.

## PROGNOSTIC SIGNIFICANCE OF LABORATORY DATA

The average white-cell count for all patients in this series was 22,000, with a high percentage of polymorphonuclear cells in the relatively small number of cases in which differential counts were done. The pulse rate averaged 114 in the very ill patients and 106 in those who were not very ill. In no case was the admission temperature over 103.5°F., and in nearly one third (30 per cent) it was under 100°F. by mouth. These facts served merely to confirm the preoperative clinical diagnosis, and the prognostic significance of the leukocyte-pulse ratio, on which we laid great

emphasis when considering the patients without mass formation, is meaningless in this series.

#### PROGNOSTIC SIGNIFICANCE OF DIAGNOSTIC ERRORS

The diagnosis in many of the cases in which the mass was not detected preoperatively was "acute appendicitis," and strictly speaking might be considered mistaken. In an indeterminate number of cases, a diagnosis of "appendiceal abscess" was made in which no appendicitis was found, and 1 such patient, in whom the diagnosis was persisted in postoperatively, died of unsuspected carcinoma of the cecum three months following discharge.

Exclusive of these errors, a mistaken diagnosis was made in nearly one tenth (9 per cent) of the cases in this series. Nearly half these (10 cases) were erroneously diagnosed as either benign (3 of ovary) or malignant (2 of cecum, 1 of colon, 1 of kidney, 1 retroperitoneal and 2 unclassified) neoplasms. With these 10 cases, as with 4 others (3 of hernia and 1 of cirrhosis and ascites), it was primarily a misconception of the nature of the mass that was the confusing factor in diagnosis. In 2 of these, the diagnosis of malignant tumor was persisted in even after the peritoneal cavity had been opened, and in both an ileotransverse colostomy was carried out as the initial step of a two-stage procedure. All the patients survived following removal of the appendix (12 cases) or drainage alone (2 cases).

In the remaining 7 cases (3 of pelvic inflammation, 2 of cholecystitis, 1 of enteritis and 1 of nephritis), a misinterpretation of the manifestations of infection gave rise to the diagnostic error. One of these patients died following surgery on the gall bladder, and a second death occurred in a patient with renal infection and diabetes who was moribund on entry and was not considered to have any surgical lesion but in whom an unsuspected appendiceal abscess was discovered at autopsy three days after admission. The other 5 patients all lived following appendectomy (3 cases), drainage (1 case) or spontaneous subsidence of the process without surgery (1 case).

Because of the possibility of revising with relative safety the original intent of the operation after the peritoneal cavity had been opened and the true nature of the lesion determined, the mortality rate for all the above cases (9.5 per cent) was only slightly higher than that in those correctly diagnosed preoperatively (6.8 per cent). This is in striking contrast to the situation found in the cases of appendiceal peritonitis without mass formation, in which an incorrect preoperative diagnosis frequently resulted in treatment that was incompatible with recovery.

#### SUMMARY OF PROGNOSTIC PREOPERATIVE FACTORS

In the patients without a mass, we attempted to estimate the relative prognostic value of certain preoperative findings by citing the contrasting mortality rates occasioned by the presence or absence of a given factor. The same procedure has been followed in Table 5 for this series of cases

TABLE 5. *Relative Prognostic Value of Various Clinical Factors, as Determined by the Mortality Rate Associated with Each Factor, Based on 227 Cases with a Total Mortality of 7.0 Per Cent.*

CLINICAL FACTOR*	MORTALITY WITH FACTOR PRESENT	MORTALITY WITH FACTOR ABSENT
	%	%
Patient very ill on admission	19	5
Patient under fifteen or over fifty years	12	1
Operation on fifth, sixth or seventh day of disease	15	5
Mass not detected on physical examination	12	5
Males	9	4
Cathartics given preoperatively	10	6
Mistaken preoperative diagnosis	10	7

\*In 18 cases with preoperative chills, there were no deaths, but this number is too small to have statistical value

in which the appendiceal peritonitis was associated with a mass. Again, it should be pointed out that this evaluation attempts merely to approximate the true prognostic significance of each factor, for these were found in such varying combinations that the accuracy of their isolated ratings can be only relative.

#### INFLUENCE OF TREATMENT ON MORTALITY RATE

##### Choice of Treatment

*No operation.* In 5 cases, no operation was carried out during the initial hospital admission. In 2 of these, the reason for withholding surgery was a mistaken diagnosis. One was the patient with an original diagnosis of pelvic inflammatory disease who gave increasingly convincing evidence during her hospital stay that the inflammatory mass that gradually subsided without operation was probably of appendiceal origin, and the other was the patient with renal damage who died three days after entry.

Of the 3 unoperated cases correctly diagnosed as appendiceal abscess, the infection in 1 was satisfactorily handled by spontaneous drainage into the rectum. Another patient was discharged against advice, only to be readmitted for an uneventful incision and drainage and subsequent appendectomy; and the third patient, a nine-year-old child whose mass subsided during a hospital stay of seventeen days, returned three weeks later with a recurrence of symptoms that necessitated appendectomy with drainage. The fact that so few pa-

tients were treated without operation lessens the value of the statistical mortality of 20 per cent for this form of treatment.

Because in this series there was only 1 case in which an inflammatory mass subsided without operation, spontaneous drainage or death, we believe that it must be extremely rare in an unoperated case for a localized mass secondary to a ruptured appendix to subside completely without drainage. The persistence of the inciting cause of the infection undoubtedly best explains why conservative treatment is so rarely effective. This is in contrast to the course of an inflammatory mass that develops following appendectomy, for such a process subsided without operation in half those cases in both this and our earlier series in which it was present during the convalescence.

*Immediate operation.* Since a mass was present in all these patients, the first consideration was when surgical attack could most safely be car-

TABLE 6. *Comparative Incidence of Immediate and Deferred Operation and the Operative Mortality of Immediate Operation.*

Averages			64	6.7

\*Note that this tabulation covers only two years instead of the three-year tabulation of the subsequent periods.

†There have been no deaths in the last 44 consecutive cases.

ried out. The urgency of operation found in many of our cases of ruptured appendix without associated masses was not a factor in this series in which the danger of spontaneous spread could be assumed to be practically nonexistent. Every patient about to undergo surgery should receive appropriate preoperative measures to combat existing dehydration, and for that reason we allowed an arbitrary time limit of six hours to carry out such measures; within this period, we still considered that operation was done "immediately." Delay beyond that period in this series of cases implies that we believed that the local process would progress to a stage more favorable to surgery if such delay was instituted.

Whereas during the first five years of this series, four fifths (80 per cent) of the patients were operated on soon after entry (Table 6), this has been true in slightly less than half (49 per cent) the cases during the last five years. This striking change in policy undoubtedly constitutes one of the

factors responsible for the downward trend of the mortality from 12 per cent in the earlier years to 3 per cent more recently.

In 143 cases, immediate operation was carried out, with a mortality of 7 per cent and an uneventful convalescence in 73 per cent of the survivors. In the cases with a history of four days or less operated on within six hours of entry, the mortality was 4 per cent, whereas during the fifth, sixth and seventh days of the disease, there was a mortality of 12 per cent in the cases treated by immediate surgery. Following the seventh day, immediate operation was attended with a 7 per cent mortality.

During the first four days of the disease, immediate operation was carried out more than ten times as often as deferred treatment, and during the fifth, sixth and seventh days, despite a mortality of 11.7 per cent, immediate operation was adopted three times as frequently as conservative observation. Later than the seventh day, the mortality for immediate operation was 7 per cent, and there was a slightly smaller number of cases in which operation was done immediately than in which it was deferred.

*Deferred operation.* In 79 cases, operation was deferred beyond six hours from the time of admission; in over half (54 per cent), the period of observation was under four days, and in the remainder it was over four days, extending as long as twenty-eight days in 1 case. The significant fact about the mortality rate of 5 per cent in all deferred operations is that 3 of the 4 deaths occurred when operation fell on the fifth, sixth or seventh day of the disease, either because an early case had been delayed too long or because a late case not long enough to exclude it from this relatively lethal period. There was no death in the group of 33 cases in which operation was deferred over four days, and there was no case in which it was established that an undrained abscess spontaneously ruptured into the peritoneal cavity.

*Appendectomy versus incision and drainage.* The policy of carrying out appendectomy as a primary procedure in slightly less than half (47 per cent) the cases has remained remarkably constant over the years studied, and the mortality rate for the 104 cases so treated was 8 per cent. It was accepted as a general surgical principle by the members of the staff during the years under consideration that operation should consist of incision and drainage alone, unless it was believed that the appendix could be removed without adding appreciably to the risk of the procedure. It is obvious from a review of the operative notes that there was a disregard of this principle in a considerable

number of cases in which a mistaken sense of pride in securing the appendix at all costs led the surgeon to persist unduly long, or with an unwarranted amount of trauma.

In 10 cases in which no drainage was instituted, the miss made out preoperatively either proved to consist of an indurated portion of the omentum without associated frank pus (8 cases) or was incorrectly taken to represent cancer at the original operation (2 cases). In all save these, cigarette drains were placed in the right gutter or pelvis, depending on the extent of the infection. A special effort was made to bring the drains out along the lateral wall of the peritoneal cavity rather than between loops of small intestine, and when some form of rectus incision was used, drainage through a stab wound was not infrequently (12 cases) employed to accomplish this end.

Incision and drainage alone as the original surgical procedure was carried out in 118 cases, with a mortality of 6 per cent, but always with the expectation that the appendix would be removed at a subsequent operation. Although the number of cases within each group is too small for definite conclusions to be drawn, the statistics (Table 7)

TABLE 7. *Comparative Incidences and Mortalities of Primary Appendectomy and of Incision and Drainage in Relation to Duration of Disease*

DURATION BEFORE OPERATION	NO. OF CASES	INCIDENCE OF PERITONITIS APPENDICITIS*	MORTALITY OF PERITONITIS APPENDICITIS	MORTALITY OF PRIMARY PERITONITIS
		%	%	%
1 to 4	56	73	7	—
5 to 7	46	43	20	13
8 or over	120	37	7	4
Total	222			
Averages		47	7	5.9

\*All the remaining cases had primary incision and drainage.

suggest that the removal of the appendix within the first four days of the disease tends to lower the mortality in a majority of these cases. Furthermore, although removal of the appendix after the fourth day adds materially to the risk, the high mortality rate when operation is done on the fifth, sixth or seventh day of the illness is accounted for not so much by the type of operation that is carried out as by the unfortunate period selected for surgery. In the significantly large number of cases in which operation was performed after the seventh day (120 cases), removal of the appendix as the original procedure nearly doubled the operative mortality, increasing it from 4 to 7 per cent.

#### Technical Factors

**Type of incision** There has been a marked increase in the use of the McBurney incision or one of its modifications at our hospital in recent

years with the belief that the danger of contamination of the general peritoneal cavity is minimized through a lateral approach. The striking finding (Table 8) that the mortality rate was less than

TABLE 8. *Influence on Mortality Rate of Type of Incision at Original Operation*

TYPE OF INCISION	AP. APPENDECTOMY NO. OF CASES	MORTALITY %	INCISION AND DRAINAGE NO. OF CASES	MORTALITY %	TOTAL OPERATIVE MORTALITY %
Right rectus McBurney	89	0	45	11	10
	15	0	73	3	2
Totals	104		118		
Averages		7		5.9	6

one fourth as high when such an approach was used instead of some form of rectus incision seems to substantiate this opinion. We believe, however, that the arbitrary selection of any one incision for all cases is unfortunate, and that the avoidance of unnecessary surgical trauma within the peritoneal cavity in certain cases can best be accomplished through a pirarectus incision, with drainage through a stab wound in the flank.

**Anesthetic** Local anesthesia was rarely used for appendectomy but was deemed the anesthesia of choice for over one quarter (28 per cent) of the patients in whom incision and drainage alone was carried out. Although ether was the agent used in over half (57 per cent) the entire series, there has been a growing tendency in more recent years toward the use of spinal anesthesia if these cases are not suitable for local novocain infiltration. The fact that the mortality rate (13 per cent) was over twice as high when local anesthesia was used as that (5 per cent) when either ether or a spinal anesthetic was employed merely emphasizes the fact that novocain infiltration was employed in a larger percentage of the poor risk cases.

**Chemotherapy** Chemotherapy was available in only the latter part of the period under discussion, and although we are now employing it routinely in patients with appendiceal peritonitis, it was used in but a single case of this series with mass formation.

#### Secondary Operation

There were no fatalities in the 76 explorations done as a secondary procedure following incision and drainage of the peritoneal cavity. In 73 of these, appendectomy was carried out between four and seven months after the first operation, and in the remaining cases, there was an almost even division between those in which the interval was under four months and those in which it was over seven.

In slightly over half (55 per cent) the cases, the secondary operation averaged forty nine minutes,

and it was apparent from a study of the surgeon's notes that the removal of the appendix was technically a relatively simple procedure; in the remaining cases, not including those complicated by such additional surgery as the repair of a hernial defect, the operation was difficult and averaged seventy-four minutes.

We were especially interested in trying to find some correlation between the lapse of time between operations and the relative ease with which secondary appendectomy could be carried out, but could discover no consistent relation between these two factors.

Although we believe that, as a general rule, appendectomy following preliminary incision and drainage should be urged as a secondary procedure to prevent recurrence of further trouble, there were 11 patients in whom, because of advanced age or poor general condition, it seemed wiser to abandon the idea of further surgery. Eight of these patients were over sixty years of age, and of the remaining 3 in their late fifties, 1 was a cardiac and another a diabetic patient. Information is not available concerning the ultimate course of these and the 24 additional patients who failed to carry out our instructions to return for secondary appendectomy.

#### COMPLICATIONS

Complications, excluding an indeterminate degree of peritonitis, which might be considered an inherent part of the original lesion, occurred in over one quarter (28 per cent) of the total series and one third (37 per cent) of the fatal cases. The difference in the incidence of cases with complications following appendectomy (23 per cent) and those with incision and drainage alone (32 per cent) was accounted for by the larger number of incisional hernias found after the latter type of operation.

The ultimate significance of the high incidence of hernias (16 cases) is qualified by the fact that satisfactory repair at the time of secondary appendectomy was effected in 9 out of 13 cases. It is worthy of note that the incidence of these hernias was higher when the McBurney incision was used for simple incision and drainage (12 per cent) than with some form of rectus approach (9 per cent).

Pulmonary disease was encountered postoperatively in 20 patients, in 2 of whom it was a contributing cause of death. The remaining 18 patients survived despite the postoperative clinical findings of atelectasis (13 cases) and pneumonia (5 cases). Although the former did not retard the patient's convalescence, the latter increased by over one week (nine days) the average time required in the hospital.

Major wound sepsis occurred in 10 cases. The average hospital stay of the survivors was lengthened from an anticipated twenty to forty days, but the only death was in a patient who also had a subphrenic abscess. One other nonfatal subdiaphragmatic abscess occurred.

Residual abscesses were noted in 10 cases and, when they did not subside (4 cases) or rupture spontaneously into the rectum (1 case), required secondary drainage by either an abdominal (2 cases) or rectal (2 cases) approach. In 1 of these cases complicated by further chronic sepsis, the patient died after fifty-four days.

The recorded occurrence of fecal fistulas in 11 cases undoubtedly referred in some to the persistent drainage of pus beyond the anticipated time rather than to the presence of a true fistula. In but a single case was it necessary to operate on a patient to correct this condition.

Although the Miller-Abbott tube was not available during the earlier years of this series, there were but 2 cases in which intestinal obstruction requiring corrective surgery developed.

Other complications encountered were phlebitis (3 cases), postoperative hemorrhage (2 cases), parotitis (2 cases), cystitis (1 case) and pylephlebitis with multiple liver abscess (1 case). Although these complications lengthened the hospital stay appreciably, only the patient with pylephlebitis succumbed.

#### *Cause of Death*

In only 1 case with multiple liver abscesses secondary to a pylephlebitis and another with uremia could it be established with any degree of certainty that death had occurred from causes other than a spread of infection in the general peritoneal cavity. The following clinical review of the deaths in this series correlated with the statistical data affords the most constructive approach to a lowering of the mortality rate.

#### PREVENTABILITY OF DEATHS

##### *Errors in Diagnosis*

One patient who was sixty-three years old and very ill might have survived had his infection not been disseminated by operation based on the mistaken diagnosis of cholecystitis.

##### *Incorrect Choice of Treatment*

Although each case must be judged as an individual problem, we wish to point out that in 6 cases the selection of the fifth, sixth or seventh day for surgery seems to us unwise in the light of our experience.

One of these patients was considered very ill on entry, but nevertheless surgery was not deferred and the patient died of general peritonitis and a complicating pneumonia fifteen days after operation. None of the remaining 5 patients were very ill on admission, and yet 3 died of general peritonitis within three days following operation. The remaining 2 survived their first few postoperative days only to succumb at a somewhat later date to prolonged intraperitoneal sepsis.

In 4 of these last patients, primary appendectomy rather than simple incision and drainage was performed, and thus it appears that the operation selected in all but 1 case was of the type that carried nearly twice as high a mortality for this stage of the disease as the alternative form of surgery.

#### *Errors in Technique*

Four patients who were not very ill on admission were operated on at a theoretically favorable period of their disease; yet all of them died of general peritonitis within five days of operation. None of these procedures were unduly protracted, and the implication is that the operative technique was primarily at fault.

#### *Unavoidable Deaths*

One of these 5 patients, previously mentioned as having an appendiceal abscess as an incidental and unsuspected finding at autopsy, entered the hospital in a moribund condition and promptly died of uremia without operation. Another patient had a protracted hospital stay of sixty days and finally died of multiple liver abscesses secondary to pyelephlebitis. The 3 remaining patients fell into the very young or very old age groups. All were very ill on entry, and it would have been difficult to have improved the treatment that was instituted.

So long as the diagnosis of appendicitis continues to be deferred until perforation has taken place, a group of patients will persist whose deaths may be said to be "unavoidable" only so far as the term refers to a condition that has become established as a result of erroneous earlier diagnosis and ill advised treatment.

#### CONCLUSIONS

The following conclusions seem justifiable:

Patients with appendiceal peritonitis with mass formation present a very different clinical entity and therapeutic problem from those found in cases of appendiceal peritonitis without mass formation. The treatment in such cases is surgical.

Operations should rarely be done on the fifth, sixth or seventh day of the disease.

If a policy of deferring operation is adopted, it had best be pursued for at least four days.

The abdomen in all cases of appendiceal peritonitis should be carefully palpated under anesthesia before operation, and if a mass is discovered at that time, the plan of treatment should be reevaluated and operation possibly postponed.

If the presence of a laterally situated mass is not appreciated until after the peritoneal cavity has been opened, any medially placed original incision should be closed and drainage instituted through a McBurney incision.

A McBurney incision or one of its modifications, rather than some form of rectus approach, should be used for both appendectomy and simple incision and drainage, unless the mass lies unusually far toward the midline, when operation through a pararectus incision, with drainage through a laterally placed stab wound, should be considered.

Incision and drainage alone should be done as a primary procedure unless the technical removal of the appendix can be readily accomplished. Observance of this principle is especially important after the fourth day of the disease.

Appendectomy should be carried out within six weeks following incision and drainage unless the patient is in generally poor condition or some complication provides an indication for a longer interval between operations.

Even when a localized mass has formed, the general clinical impression that the patient creates at entry of being very ill or not very ill is of more reliable prognostic significance than any laboratory data.

# RETINAL LIPEMIA AND VISUAL DISTURBANCES ASSOCIATED WITH ACROMEGALY AND DIABETES MELLITUS

## Report of a Case

JOSEPH IGRSHEIMER, M.D.\*

BOSTON

THE following case of acromegaly with diabetes mellitus and retinal lipemia was studied in the Eye Department and also in the Medical Department at the State University in Istanbul, Turkey. It is reported because of its ophthalmologic and endocrinologic interest and because of its clinical bearing on the experimental work in this field.

### CASE REPORT

A 35-year-old man was admitted to the Eye Clinic on April 16, 1939, almost blind. He was over 6 feet tall and was definitely acromegalic. Examination and history pointed to a tumor of the hypophysis. The patient suffered from polyphagia and polyuria; there was complete disappearance of the libido, and x-ray study showed a markedly enlarged sella turcica. Four months previously, he had an illness with fever, and sugar was found in his urine. There was a slight odor of acetone to his breath.

There was a certain amount of exophthalmos in both eyes. Ophthalmoscopic examination showed a definite retinal lipemia, but no other abnormality.

The vision was reduced on both sides to seeing movements of the hands. On the right, a field could not be taken; on the left, in the upper nasal quadrant, a small

fields. However, the findings in the blood and urine remained unchanged.

On May 8, in addition to the insulin, posterior pituitary extract was given parenterally. On May 18, vision on both sides had improved to 5/10 in both eyes. The nasal part of the visual fields was almost normal, a bitemporal hemianopia being present. The sugar content in the urine, however, had not changed. The ophthalmoscopic findings were normal.

On May 20, the insulin was omitted, but the pituitary extract was continued.

On May 31, the patient did not feel well, and the eyes showed a turn for the worse; the vision in the left eye had decreased to 5/20; in the right it was 5/6. The sugar in the urine varied between 2.3 and 3.1 per cent.

On June 3, all medication was discontinued. On June 12, there was a further decrease in vision: 5/10 in the right eye, and 5/35 in the left. The nasal parts of the fields were again somewhat involved. The patient had lost 4 pounds. Two days later, the general condition was worse. Vision on the right was 5/20, and on the left 1/10. Ophthalmoscopic examination showed a return of the lipemia as seen in the beginning. Between June 3 and 13, the sugar in the urine remained unchanged.

On June 13, a course of x-ray treatment was given to the pituitary gland, and on June 25, the general condition was again improved. Vision went up to 5/7 on the right and 5/20 on the left. There was bitemporal hemianopia. On July 11, vision was 5/7 on the right and 5/15 on the left. The fields were unchanged, but the patient could occasionally see some movements in the temporal fields. The lipemic condition in his eyes had again disappeared.

The patient was discharged on July 15. He did not return for further x-ray treatment.

A diagnosis of tumor of the pituitary gland, complicated by diabetes mellitus, was made. There was no increase in the excretion of nitrogenous substances, no ketonuria and no ketonemia. Most remarkable was the increase of total fat and cholesterol in the blood, and in connection with this general hyperlipemia, there existed a very marked retinal lipemia. Besides the retinal change, the patient showed other unusual eye disturbances.

The retinal lipemia in this case was absolutely characteristic. It is not necessary to describe the clinical picture fully, since many descriptions and pictures are available in textbooks and other publications.

### DISCUSSION

It is well known that glycosuria and even severe diabetes, with and without coma, may occur with acromegaly. The relation of the pituitary gland to the carbohydrate metabolism was clarified by clinical studies and the fundamental experimental investigations of Cushing and Davidoff,<sup>1</sup> Houssay

TABLE 1. *Blood Chemical Findings.*

\*Normal, 500 to 800 mg. per 100 cc.

area of the nasal field still remained. Diastolic pressure in the retinal vessels was 40 mm. of mercury on both sides, with a general blood pressure corresponding to the patient's age.

The sugar and fat content of the blood is shown in Table 1.

There was 3.3 per cent sugar in the urine, but no albumin or acetone.

The basal metabolic rate was normal.

The patient was transferred to the Medical Department on April 22, and 5 days later he was started on insulin (the first 2 days, 40 units; then, 100 units daily) and diet.

By May 5, his general health had improved markedly; his color was much better, and he was cheerful. Vision in the right eye was 1/25, and in the left eye 5/35. There was definite improvement of the nasal part of the visual

and Biasotti,<sup>2</sup> Young<sup>3-5</sup> and others. According to the recent studies of Best et al.<sup>6,7</sup> and of Young, there is no pituitary diabetes without involvement of the pancreas. After injection of anterior-lobe extract, with resulting diabetes, an extensive fall in the insulin content of the pancreas and microscopic changes in the islands of Langerhans were noted. One must assume that the pancreatic disease and the lack of pancreatic hormone can be caused by a hypersecretion of pituitary diabetogenic hormone.

The relation of the pituitary gland to fat metabolism is not so clear as that to carbohydrate metabolism. The assertion of Anselmino and Hoffmann<sup>8</sup> and Raab<sup>9</sup> that substances secreted by the pituitary influence the fat metabolism is not yet proved.

Has pituitary diabetes any characteristic features of regular diabetes? Clinically, von Noorden<sup>10</sup> has pointed out that the glycosuria of patients with acromegaly is not influenced so easily by change of diet as the ordinary diabetes is. Alternating hyperglycemia and hypoglycemia in rather sudden changes was seen by Goldschmidt.<sup>11</sup> His case showed acromegalic symptoms and bony destruction of the sella without enlargement; at autopsy, no lesion of the pituitary gland was found even on microscopic examination. According to Joslin et al.,<sup>12</sup> the diabetes found in acromegaly or other pituitary disease does not differ essentially from ordinary diabetes, but it varies from time to time according to the activity of the hypophysis, and as a result a spontaneous temporary or permanent cure of the pituitary diabetes may be effected. Oppenheimer<sup>13</sup> described a patient with coma who after a certain time showed a surprisingly high tolerance for carbohydrates.

The response to insulin seems to be of a certain importance in the differential diagnosis between pituitary and ordinary diabetes. Ulrich<sup>14</sup> pointed out that insulin is less effective in pituitary diabetes and recommended its use to differentiate pituitary from ordinary diabetes. This clinical experience was supported by experimental results.

The retinal lipemia in the case presented in this paper was, in its ophthalmoscopic appearance as well as in its response to insulin, similar to the published cases of retinal lipemia, none of which showed pituitary symptoms. The decrease in blood sugar and blood lipids, however, was much quicker and more marked in most of the published cases. One can say that in the case presented above there was some resistance against insulin, especially so far as the sugar was concerned, and it seems possible that the involvement of the pituitary gland had something to do with this resistance. But it must be said that in McCann's<sup>15</sup> case, which was supposedly due to an ordinary pancreatic disease, the retinal lipemia disappeared

in seven to nine days, whereas both the sugar and the lipids in the blood increased during this time under treatment consisting of 10 to 30 units of insulin a day.

After the insulin was stopped, the patient in the case discussed above became worse in every respect, and retinal lipemia recurred; however, when x-ray therapy was given to the pituitary region, all symptoms improved, and the retinal lipemia disappeared. This indicates that the pituitary lesion was related to the diabetes and especially to the retinal lipemia.

Concerning the visual disturbances, two questions arise. What was the reason for the almost total blindness of this patient? And was the involvement of the nasal fields due to the same source that caused the involvement of the temporal fields?

It would be easier to understand the total blindness if one could assume that the retinal lipemia had, because of impaired nutrition, an injurious effect on the retinal tissue. Reis<sup>16</sup> made such a suggestion, but his case was probably complicated by disease of the optic nerve. There is no doubt that most patients with characteristic lipemia who were tested for visual disturbances had normal function (Turney and Dudgeon,<sup>17</sup> Koellner,<sup>18</sup> Moore,<sup>19</sup> Hardy,<sup>20</sup> McGuire,<sup>21</sup> Wagener,<sup>22</sup> McCann,<sup>15</sup> McKee and Rabinowitch,<sup>23</sup> Chase<sup>24</sup> and Jaffe and Schonfeld<sup>25</sup>).

In some apparently uncomplicated cases, blurred vision or a slight decrease of visual acuity was found (Darling,<sup>26</sup> Rowe<sup>27</sup> and Ferber and Apperman<sup>28</sup>). Only Ferber and Apperman mention that the visual trouble ceased after disappearance of the retinal lipemia. Machlis's<sup>29</sup> patient suffered from diabetic coma with retinal lipemia; when the patient recovered from the coma, he was "virtually blind," but the retinal lipemia subsequently disappeared, with a full return of the visual capacity. This case, complicated by a transient coma, cannot be compared with a case like the one presented above.

It is true that in this case the improvement of the retinal functions was simultaneous with the disappearance of the retinal lipemia and that the decrease of the vision after the insulin was stopped was accompanied by a recurrence of the retinal lipemia. Nevertheless, I cannot believe that the functional disturbance was produced by the lipemic state of the retinal vessels, because in most cases, the lipemia is harmless to the retinal tissue, and it is quite unlikely that in a few exceptional cases the retina could be damaged by lipemia. Furthermore, the effect of x-ray treatment cannot be explained by the assumption that the visual disturbance was caused by retinal disease.

It seems more probable that the effect of both therapeutic agents (insulin and x-ray) was due to their influence on the pituitary-diencephalic region. The pituitary tumor was responsible only for a bitemporal hemianopia, which was very resistant to treatment. Perhaps a second series of x-ray treatments would have brought some results, because after the first there was a slight improvement. It is quite unlikely, however, that the involvement of the nasal visual fields was due to a growing tumor, because in such a case the involvement of the uncrossed chiasma fibers occurs at a relatively late stage, when there is already an optic atrophy. The disks in the patient under discussion were absolutely normal, and the prompt success of the insulin therapy is not in favor of such an assumption.

It is more probable that besides the tumor pressure another process was present in the pituitary-diencephalic region and that this process caused a temporary interruption of the whole optical pathway on both sides. It was influenced by insulin as well as by x-ray therapy, as demonstrated by the improvement of the central and peripheral vision. But the improvement of the peripheral function was seen only on the nasal fields, because the temporal fields (the crossed nerve fibers) were blocked by the tumor pressure. I assume that the tumor hemianopia was superimposed on the other disturbance, which involved nasal and temporal fields at the same time—in other words, that there were two different conditions acting at the same time on the eye apparatus in the chiasmal region. Whether besides the tumor pressure there was an influence on a center in the pituitary gland or somewhere else in the diencephalic region, I do not know. One can be quite sure that the initial improvement, then deterioration and then improvement again were not mere accidents, since the turn for the worse started again as soon as the insulin was omitted.

Some experiences of Zondek<sup>30</sup> and Feigenbaum<sup>31</sup> are notable. The former has drawn attention to a condition that he calls "salt-water obesity." The main symptom is chronic headache, which, according to him, is due to an increase of cranial pressure; he believes that this increased pressure is caused by a retention of water and salts in the cerebral tissue. The localization of this condition in the vicinity of the chiasm could be considered probable by bitemporal hemianopic defects (according to Feigenbaum) that disappeared as did the headache after dehydration therapy and other measures causing the removal of the salts. In Zondek's case, in which the sella turcica was enlarged and there were genital symptoms besides the headaches, the bitemporal hemianopia for colors also disappeared after such thera-

py. This fact showed, according to Zondek, "that not only the pressure of a growing tumor (probably a chromophobe adenoma) caused the changes in the field of vision, but that also processes responsive to therapy, in the vicinity of the tumor, were causative factors."

These observations of Zondek and Feigenbaum and the case reported are different in many respects, but they seem to have one point in common: that pituitary disease may influence the optic pathways not only directly by the pressure of an existing tumor but also in a more indirect way. If this could be confirmed by further observations, it would be interesting from an ophthalmologic as well as from an endocrinologic standpoint.

### SUMMARY

A case of acromegaly complicated by diabetes mellitus with retinal lipemia and peculiar visual disturbances is described and discussed.

## CLINICAL NOTE

### HAMARTOMA OF THE SPLEEN: REPORT OF A CASE

RICHARD H SWEET, M.D.,\* AND  
SHIELDS WARREN, MD†

BOSTON

A RECENT experience with a case of hamartoma of the spleen, because of the rarity of the condition, prompts us to report this case in some detail.

There are few references to this tumor in the literature, and the standard textbooks of pathology refer to it only briefly. Hamartoma is a tumor composed of tissue, present in excess beyond normal requirements, that can hardly be distinguished from the normal but possesses a limited capacity for aberrant growth. These tumors are benign and clearly demarcated, and often attain a fairly large size. To those of the spleen, the term "splenoma" has been applied. The age of the patient varies. The tumor is probably of congenital or of embryonic-rest origin, and usually attracts attention only by its size. In 6 patients—4 men and 2 women—reported by Mordasini,<sup>1</sup> the ages ranged from twenty-three to eighty-four years. In all, the spleen was enlarged with a clearly demarcated mass or masses that simulated the splenic tissue, but varied in details of histology and arrangement. The only symptoms were those of splenic enlargement. Apparently, the function of the organ was not disturbed. In Fischer's<sup>2</sup> case, that of a forty-two-year-old man with splenic enlargement, the spleen weighed 2100 gm. These tumors have occurred in animals<sup>3</sup> as well as in human beings.

The description and illustration of the histologic findings in this case may help to further the understanding of this rare splenic tumor.

#### CASE REPORT

Mrs. J. F., a 59-year-old Italian-born housewife, was referred to the clinic of the Palmer Memorial Hospital because of swelling of the abdomen. She had been obese as long as she could remember, but stated that since 8 months previously her abdomen had been growing disproportionately

larger. She had consulted a chiropractor first, but failing to obtain relief had gone to her regular physician, who discovered that she had an abdominal tumor. It was also discovered that she had diabetes, she had never taken insulin, however. During the previous 4 months, she had become unusually constipated, having to resort regularly to the taking of laxatives.

The patient had had no serious illnesses and no operations. She had been married for 38 years and had had thirteen children, of whom eight had died in infancy or childhood. She had had four miscarriages. She had had no menstrual periods for several years and had had no vaginal bleeding or discharge.

Physical examination showed a short, obese woman weighing 186 pounds—17 pounds less than she had weighed 6 months previously. The heart appeared normal, except for a soft, blowing systolic murmur over the entire precordium. The blood pressure was 120/80. In the left side of the abdomen was a large, firm tumor mass about 25 cm in diameter. It was easily moved about, but not so freely as many ovarian tumors of that size. Its chief point of attachment was apparently in the upper quadrant rather than in the lower. Bimanual examination of the pelvis revealed a prolapsed but otherwise not abnormal uterus. There was no demonstrable connection between the tumor and any of the pelvic viscera.

Laboratory examinations revealed a red cell count of 3,730,000 with a hemoglobin of 67 per cent, and a white-cell count of 8750 with 76 per cent polymorphonuclears, 16 per cent lymphocytes, 7 per cent large mononuclears and 1 per cent eosinophils. The platelets were normal, and the red cells showed slight poikilocytosis and anisocytosis. The blood sugar was 110 mg, and the cholesterol 141 mg per 100 cc. The blood Hinton reaction was negative, and the urine was essentially normal.

X-ray examination showed a large mass, approximately 17 cm in diameter, in the left side of the abdomen, with its medial border at the lateral psoas margin and its lower border just below the iliac crest. Its outline was relatively smooth.

A preoperative diagnosis of cyst of the spleen was made, and splenectomy was performed on August 2, 1940.

The abdomen was opened through a long, left rectus-splitting incision. The tumor was about the size of a large grapefruit and lay in the substance of the spleen. It felt soft, as though it might be a cyst or perhaps a large hemangioma. It involved the lower but not the upper pole. The vessels of the splenic pedicle, which were very large, were cut between hemostats and tied with a heavy silk ligature. The smaller vessels along the lateral margin and the vasa brevia were tied separately with chromic catgut. There was practically no bleeding during the operation. After it was made certain that the vessels were securely tied, the rest of the abdomen was hastily explored, but nothing abnormal was found except that the gall bladder was distended and contained stones. There was one large stone impacted in the ampulla. Nothing was done about the gall bladder, and the wound was closed in layers in the usual way.

During the first few days, the patient had a moderate elevation of temperature, with a cough and thick yellow sputum due to partial atelectasis at the bases of both lungs.

\*Attending in surgery Harvard Medical School assistant surgeon Palmer Memorial Hospital  
 †Assistant professor of pathology Harvard Medical School pathologist to the Harvard Cancer Commission and to the New England Deaconess and New England Baptist and Fitchburg State hospitals

By the end of a week, this had all subsided, and the convalescence from that time on was completely uneventful. The wound healed well. The patient was discharged on the 16th day after operation.

tissue by a clearly defined capsule. The tissue here was deep brownish red and finely trabeculated, and showed small vessels, as well as ill-defined malpighian follicles. The rest of the spleen was normal in color

FIGURE 1. *Surface of Spleen, Showing Circumscribed Character of Nodule.*

*Pathological report.* The specimen consisted of a spleen weighing 1120 gm. and measuring 23 by 17 by 7 cm. The surface was smooth, glistening and reddish gray. The lower two thirds was bulbous, with promi-

and showed normal trabeculations and malpighian corpuscles. Microscopically, the splenic tissue proper was not remarkable, although somewhat hyperemic. Within the encapsulated nodule, there was an irregular

FIGURE 2. *Cross Section of Spleen, Showing Resemblance of Tumor to Splenic Pulp.*

nent capsular veins. The consistence was almost cystic; the tissue at the upper pole was moderately firm. On cut section, the lower two thirds was well demarcated, but not separated from the remaining normal splenic

increase in fibrous stroma and some replacement of the pulp by fibrous tissue. The structure of the sinusoids, trabeculae and malpighian follicles was fairly well maintained. A few plasma cells were present

about some trabeculae. Rare foci of erythropoiesis occurred in the tumor. The hamartoma was not clearly encapsulated, but was of even contour and sharply defined from the normal splenic tissue, and had an incomplete pseudocapsule made up of compressed trabeculae. In the hamartoma, the malpighian corpuscles were present, but ill defined. There were scattered megakaryocytes in the pulp. Many of the sinusoids were fairly heavily congested. Diagnosis: hamartoma of the spleen.

### SUMMARY

A case of splenic tumor due to hamartoma is reported. This is a benign congenital neoplasm reproducing the structure of the spleen.

## MEDICAL PROGRESS

### ENDOCRINOLOGY: TREATMENT OF ABNORMALITIES OF THE ANTERIOR PITUITARY GLAND

JOSEPH C. AUB, M.D.,\* AND DAVID KARNOFSKY, M.D.†

BOSTON

THE anterior pituitary gland, by means of its secretion of tropic hormones, directs growth, regulates the activity of the adrenal cortex and the thyroid gland, stimulates the gonads and leads the ovaries through their complicated cycles, influences carbohydrate and probably protein and fat metabolism and takes on the additional task during pregnancy of influencing mammary development and function. The peripheral endocrine glands, stimulated by the pituitary secretions, form their specific hormones, which not only exert widespread actions but also effect and determine the further activity of the pituitary gland. A dynamic and orderly relation exists, which is not a true equilibrium, since the whole system is continually altering or readjusting itself. This discussion is limited to the treatment of disorders of the anterior pituitary gland that upset its normal relations.

Disorders of hypoactivity result when the pituitary gland diminishes its control over a single or a group of peripheral endocrine glands (as in Simmonds's disease), or when the peripheral gland is diseased, absent or unable to respond regardless of pituitary prodding—as the ovary acts during the menopause. Treatment can be stimulatory by means of specific pituitary hormones if the target gland is capable of responding, or by means of substitutive materials that replace the secretion of the target gland if that organ is not capable of responding. Pituitary hyperactivity may goad the peripheral organs on to renewed and excessive ac-

tivity, as in acromegaly, or the end organs may get out of hand and set up autonomous control, as in primary adrenocortical tumors. Treatment consists of surgery, radiation or the use of hormones or other substances to alter the internal milieu leading to a suppression of the overactive gland or to a possible diminution of the activity of its hormones. The more important materials and methods available for treatment are discussed below.

### AVAILABLE METHODS OF TREATMENT

#### *Pituitary and Related Hormones*

Attempts to make the various fractions of the pituitary gland available for treatment have been extensive, but numerous technical difficulties exist. The gland does not store its secretion in quantities, since its hormones may be elaborated only as needed, and large numbers of glands are necessary to obtain a useful amount of hormone. The number of pituitary hormones that exist is uncertain, but they appear to be numerous. They are probably protein substances, and it is proving very difficult to devise techniques for separating, extracting and purifying them without alteration or loss of potency. Finally, since they have not been characterized chemically, biologic assay is necessary. This is usually involved, expensive and difficult to interpret, and often requires considerable amounts of the hormone to be tested. Also, bioassay is not a certain means of establishing the individual identity of a hormone, since the same substance may give multiple effects. Owing to these impediments, progress has been slow.

Extraction for pituitary secretions is usually done in aqueous, acid or alkaline solutions.<sup>1</sup> The hormones may be precipitated by organic solvents, or by the use of increasing concentrations of salts at

TABLE 1. *Present Status of Purified Pituitary and Related Hormones*

HORMONE	ACTION	POTENCY OF PURIFIED PREPARATIONS <i>per mg.</i>	CONTAMINATING HORMONES	MOLICULAR WEIGHT	CHARACTERISTICS ON PROTEIN	CHARACTERISTICS ON CARBOHYDRATE	OTHER CHARACTERISTICS
Follicle stimulating hormone (FSH)	Stimulates follicle growth in the ovary and spermatogenesis in the testis	200 <sup>7</sup> to 500 <sup>8</sup> rat units	Slight amount of LH <sup>1</sup>	Not available	Only pituitary hormone in the albumin fraction <sup>1</sup>	15% <sup>3</sup> to 18.7% <sup>6</sup> carbohydrate, probably in amine, amylase will destroy hormonal activity <sup>4</sup> , 1.4% to 8.0% <sup>6</sup> hexosamine	Probably has an -S-S- (disulfide) linkage
Luteinizing hormone (LH) or interstitial cell stimulating hormone (ICSH)	With ICSH causes ovulation and corpus luteum formation, stimulates interstitial tissue of the male and female gonads	200 <sup>7</sup> to 500 <sup>8</sup> rat units	None <sup>2</sup>	About 90,000 in the pig, <sup>9</sup> 40,000 in the sheep <sup>7</sup>	Contains 1.0% tryptophane in the sheep <sup>7</sup> and 3.9% in the pig <sup>10</sup>	2.8% <sup>3</sup> to 4.15% <sup>7</sup> hexose, probably in amine, 2.2% <sup>6</sup> to 3.8% <sup>6</sup> hexosamine	Probably has an -S-S- linkage
Pregnant mare serum (PMS) or equine gonadotropin	Stimulates follicle formation and luteinization	4000 to 7000 rat units <sup>10</sup>	None	Calculated to be 30,000 <sup>11</sup>	Contains tyrosine and tryptophane <sup>11</sup>	11.1% <sup>11</sup> to 17.6% <sup>1</sup> hexose, probably in amine, 8.4% <sup>6</sup> hexosamine <sup>1</sup>	Activity is destroyed if the free amino groups are blocked out <sup>11</sup>
Chorionic hormone of pregnancy urine (APL)	Probably is a luteinizing and interstitial cell stimulating hormone	8000 rat units <sup>12</sup>	None	About 100,000 <sup>12</sup>		10 to 12% hexose, probably in amine <sup>1</sup>	Activity is not destroyed if the free amino groups are blocked out <sup>11</sup>
Lactogenic hormone	Maintains lactation, stimulates the crop gland in the pigeon	10,000 local pigeon units <sup>13</sup>	None	About 26,500 <sup>14</sup>	Contains tyrosine and tryptophane <sup>15</sup>	No carbohydrate	Activity is destroyed if the free amino groups or tyrosine is blocked out
Growth hormone	Maintains growth in hypophysectomized animals	100 hypophysectomized rat units <sup>17</sup>	Slight amount of thyrotropic hormone <sup>1</sup>	Not available	In the albumin fraction <sup>16</sup>	Almost free of sugar <sup>17</sup>	Not inactivated by cysteine, and there is probably no -S-S- linkage <sup>3</sup>
Thyrotropic hormone	Stimulates the thyroid gland	150 chick units <sup>17</sup>	Slight lictogenic, adrenotropic, growth and FSH activities, considerable LH <sup>17</sup>	Not available	In the albumin fraction <sup>16</sup>	3.5% hexose, 2.5% hexosamine <sup>17</sup>	Probably has an -S-S- linkage <sup>17</sup>
Insulin <sup>18</sup>	Lowers blood sugar, exerts antidiabetogenic action	21 international units	None	20,000 to 37,000	Typical protein, amino acid constituents have been almost completely analyzed	None	3.2% sulfur, contains an -S-S- linkage, x-ray diffraction patterns show it to be similar to most proteins

\*The unit of each pituitary hormone, when accurately noted, has an involved definition because conditions of bioassay must be so clearly delineated. It is therefore not possible to present these details here, but one unit is usually the amount that will produce the minimal detectable response in the particular end organ measured in a given species of animal. The test animal used is noted on the chart, but the unit for a given hormone is of no comparative value with that of any of the other hormones.

varying hydrogen ion concentrations. After selective precipitation of each fraction, methods are available to inactivate the contaminating substances, leading to a more homogenous preparation of the desired hormone. This relatively purified material is then bioassayed by numerous technics to determine the amount of the desired hormone and the presence of active hormonal contaminants. Some of the pituitary hormones have been analyzed chemically, and their reactions to different materials studied. They have been examined by electrophoresis and in the ultracentrifuge to determine their homogeneity and molecular weight. By these procedures, the growth, thyrotropic, adrenotropic, lactogenic, follicle-stimulating and luteinizing secretions of the pituitary gland have been isolated and studied. Similar observations have been made on the chorionic hormone of pregnancy urine and on the equine gonadotropin found in pregnant-mare serum. Table 1 shows the present status of these substances. It is of interest to compare these observations to what is known of insulin, a protein hormone that has been available in large quantities in crystalline form for about fifteen years.

There has been some hope that the various pituitary hormones represented prosthetic groups, which were relatively simple, ultimately synthesizable molecules attached to a protein carrier—for example, thyroxine on a globulin. This has not been proved, and the pituitary hormones appear to be individual homogenous proteins. Extraction is difficult, the hormones are not attainable in large quantities, and synthesis appears remote. Unless available sources for these materials improve, as those of the chorionic and equine gonadotropins have, hope for adequate, clinical pituitary therapeutic agents is scant.

Another obstacle in the use of pituitary substances is that they all seem to stimulate in the host the formation of substances referred to as anti-hormones, which neutralize their activity. The literature has been adequately reviewed,<sup>19, 20</sup> and the general opinion formed that antihormones are immune bodies developed against proteins, either those extracted with hormone or the pure exogenous hormone itself. There is at present no evidence that patients injected with and refractory to pituitary hormones inactivate their own secretions.<sup>19</sup> Although it has been observed that the purer the pituitary hormone the less the anti-hormone formation, it is not likely, because of species differences, that the very pure preparations will give no antihormone formation. At least in the luteinizing<sup>7</sup> and lactogenic hormones,<sup>15</sup> species differences in even the most purified preparations have been found. From a practical point of view, three to six weeks after the continued admin-

istration of a pituitary hormone, the antihormone titer gradually increases until the hormonal effect is completely neutralized. When the treatment is stopped, the antihormone titer usually disappears almost as rapidly.<sup>19</sup> Pituitary and related hormones should therefore be given in courses of six to eight weeks, followed by rest periods of similar duration. Gradually increasing amounts during a given course and alternation of the type of pituitary preparation, in both the animal source and the method of extraction, may diminish the antihormone influence and enhance the efficacy of the treatment.

On the market today are various pituitary and related preparations, mostly in an uncertain state of purification.<sup>21</sup> They deteriorate in aqueous solution on standing, and the dried pituitary powders are more satisfactory for storage. All these materials must be given parenterally, and care for specific sensitivity should be observed, particularly with pregnant-mare serum. The preparations available are as follows:

#### *Whole pituitary substance.*

*Growth hormone.* This is impure and of varying potency, and the usual dose is about 1 to 3 cc. daily to three times weekly.

*Lactogenic hormone.* Although fairly pure, the hormone has proved of little clinical value.

*Thyrotropic hormone.* Extracts of this material contain most of the other pituitary hormones, but its thyrotropic activity is usually about 200 chick units per cc. In man, it gives definite effects in responsive thyroid glands, and it is of some value in diagnostic tests in determining the ability of the thyroid gland to respond to pituitary stimulation.<sup>22</sup>

*Gonadotropic hormones.* Purified pituitary gonadotropins are not generally available, but a pituitary extract (called the synergic factor and said to contain mostly gonadotropic hormone<sup>23</sup>), in combination with the chorionic hormone, is reported to give a marked gonadotropic effect. Otherwise, the chorionic hormone is of little value clinically except in the treatment of selected cases of undescended testes.<sup>24</sup> It is available in solutions containing 100 to 500 international units per cc., the usual single dose. Pregnant-mare serum is a potent gonadotropin, but its usefulness is disputed. It is available as a powder and can be made up to solutions containing 500 international units per cc.

Each of these gonadotropins has its peculiar properties, and their proper use is most complicated and not well understood. When they are given sequentially or coincidentally or when estrogens are added, augmentation and modified effects are observed. These hormones may be eminently satisfactory when their technic of use is clarified, and they can be given with some hope of anticipating the result. At present, indications for their use are very limited.

#### *Substitutive Therapy*

In contrast to the rather gloomy pituitary picture are the brilliant successes attending the isola-

tion, purification and in many cases the synthesis of the secretions of the peripheral endocrine organs. Of even greater significance is the discovery of synthetic materials, chemically dissimilar to the hormones but possessing some of their physiologic activities. Today, one may use thyroid, parathyroid, insulin, adrenalin, the various adrenocortical, testicular and ovarian steroids, diethylstilbestrol, methyl-testosterone and dihydrotachysterol to obtain consistent effects that stimulatory treatment will not give. It is impossible to discuss here the extreme ramifications of the use of these substances, except to note that in most cases they are more satisfactory than pituitary hormones, since they are very potent and the dosage can be controlled. They are also relatively inexpensive, and except for parathyroid hormone, produce no significant antihormone effect. The thyroid and some of the steroid hormones, such as testosterone,<sup>27</sup> stimulate the pituitary gland in small doses. Large doses of gonadal hormones, on the other hand, definitely inhibit some of the pituitary activities.<sup>26</sup>

### X-Radiation

X-radiation is extensively used in the treatment of overactivity and tumors of the pituitary gland. In the various functional and obscure disorders, the indications, dosages and dangers are not yet clearly defined. Considerable work must be done on the differential susceptibilities to x-ray of the various pituitary functions at different ages and stages of activity. It is well to remember that pituitary activity is of different significance at different ages. In childhood, it is necessary for growth and for stimulating the target glands to the increased activity essential to normal maturation. In adult life, its usual functions are most manifest in the sex cycles and during the alterations of pregnancy and lactation. After the clinical use of this function continues, but some of the target glands fail to respond to the stimulatory therapy, these relations to age and function are major considerations and, particularly, the treatment of overactivity of the pituitary must not be neglected. If the most sensitive cells are those sensitive to x-ray, this is an important point. Studies of the hormones excreted in the urine after hypophysectomy, similar to observations following the removal of the pituitary gland, have yet to be done. In surgery, it is obvious that all pituitary gland may be destroyed, but the possibility, although unproved, of selectively influencing certain cells. There are favorable reports of pituitary irradiation in

treatment on the pituitary gland, its general use cannot be advocated. The pituitary functions are too vital for the gland to be indiscriminately exposed to irradiation.

On the other hand, in the treatment of hypophyseal tumors, more radical therapy is justifiable, and x-ray therapy appears to be of great value. About 20 to 25 per cent of all intracranial tumors are of pituitary origin. Approximately three quarters of these tumors are of the nonfunctioning chromophobic type and are fairly sensitive to x-rays, except for the cystic type, which makes up about 14 per cent of the chromophobic tumors.<sup>31</sup> Clinically, these two groups cannot be distinguished, but it is commonly agreed that hypophyseal tumors deserve a trial of irradiation before surgery is undertaken.<sup>34</sup> Although there is some question whether this clinical dictum applies in the presence of serious interference with vision, it has been pointed out that x-ray treatment in these cases is often of as much or as little avail as surgery. Since pituitary tumors have such a varied history, the criterion of successful treatment is not so much the prolongation as the enhancement of life—that is, the remission of symptoms and the salvage of sight. In this respect, x-ray therapy is superior to surgery, since it has no operative mortality and less morbidity.<sup>35</sup> If an adequate trial of x-radiation is unsuccessful and there is evidence of progression of the disease, surgery is advised. If surgery is resorted to, the immediate results and prevention of recurrence are considerably improved by postoperative x-ray therapy.<sup>36</sup>

Acidophilic adenomas are small, grow slowly, and compose 20 to 25 per cent of the chromophilic adenomas.

hope for adequate agents is scant. in the use of pituitary all seem to stimulate of substances refer to neutralize their action adequately reviewed. Then formed that: developed again with hormone. There patients injected with pituitary hormone inactivation, it is differences, that: no antihormone "zing" and 1

growth and development. The effect of heredity is well known but often not adequately considered. If the patient is found to be large boned, stocky or hirsute, this is perhaps due to heredity and not to the postnatal activity of the endocrine glands. Draper<sup>37</sup> has pointed out the complexity of individual structure and notes that "sex is something more than the mere presence of a gonad." One cannot presume to change the basic stuff of man with hormones. In fact, it appears clear that therapeutic effects from hormones are usually dramatic only when the hormone is needed and that constitutional deviations are not much influenced by their use.

The consequence of environmental, regional, socioeconomic, secular, psychic and medical factors must be understood.<sup>35</sup> For example, the growth of children varies in different regions; children in California are taller than those elsewhere,<sup>33</sup> and great variations appear to be normal in the onset and rate of maturation. Large amounts of data that are essential to help delineate the broad category of normal for each person are being accumulated.<sup>40-42</sup> One must avoid turning a normal child in transition, or a lazy, overindulged person, into an endocrine problem.

#### *Dwarfism*

The evaluation of successful therapy necessarily derives from the accuracy of diagnosis. Dwarfism due to chronic disease or nutritional inadequacy requires treatment of the underlying condition, and it is not yet established whether therapy with endocrine preparations influences the growth of such dwarfs. Cretins and hypothyroid children have definite diagnostic criteria,<sup>43-44</sup> and thyroid stimulates excellent growth so long as the epiphyses of bone are ununited, although the growth factor of the pituitary gland has no effect.<sup>45</sup>

The hypopituitary dwarf (Lorain-Levi type) is delicate, well proportioned and sometimes bright. He has a normal basal metabolic rate, a high sugar tolerance and marked retardation of epiphyseal development, and is neuter in his body configuration and much retarded in sexual development. If possible, treatment should be started early and continued over an extended period. Pituitary growth hormone has been widely used, and although results have been occasionally reported as successful,<sup>46</sup> they are usually variable and inconsistent.<sup>47</sup> The chorionic hormone is probably more useful, apparently inducing a growth response through stimulation of the testes.<sup>48, 49</sup> On the whole, the use of pituitary and pituitarylike hormones to stimulate growth has been a depressing chapter. This may well be due to the quality of hormones available, for the amounts necessary for good effects are large and the antihormones that may develop are very limiting factors. It must be realized,

that growth is a slow process and that prolonged therapy is essential. We have repeatedly tried to stimulate retarded growth by such therapy and the results have never been dramatic and not much in excess of the growth of preceding years. It appears that the pituitary gland has a highly specific growth hormone, and it is unfortunate that its therapeutic effects are not more obvious in this very important problem. As available hormones improve, better results may be obtained, but at the present time, better stimulation of growth can be elicited by the use of peripheral hormones rather than by those derived from the pituitary gland.

The use of testosterone to stimulate growth is still in the experimental stage, but it seems to be the simplest and most effective way. It may act through a stimulatory effect on the pituitary gland,<sup>50</sup> but it also is probable that it has an immediate specific action in causing nitrogen and calcium retention and in inducing muscle growth.<sup>50</sup> It may be given as testosterone propionate, 10 to 25 mg intramuscularly twice weekly,<sup>51</sup> or as methyl testosterone, 10 to 25 mg by mouth daily.<sup>50</sup> The patient should be carefully watched for the occasional undesirable side reactions of the drug, such as hirsutism, macrogenitalism and edema.

Since this treatment is new, several problems must be considered. In striking cases, the appropriate age for starting treatment appears to be early. The hazards of testicular injury, premature closure of the epiphyses and macrogenitalism are more than compensated for by the possibility of removing the patient from the dwarf category. In less obvious dwarfism, it is wiser to delay conservatively because of the striking variations in growth rate that normally develop at puberty. One aid in this decision rests with the skeletal development, which in true pituitary deficiencies is much retarded. So long as the epiphyses are ununited, growth is possible, and the bone age therefore indicates the urgency for treatment. Little growth is to be expected by any therapy after union of the epiphyses. There is some evidence that methyltestosterone is more specific for growth than testosterone propionate,<sup>50</sup> and this suggests the possibility of finding an even more specific growth-stimulating steroid hormone with minimal androgenic activity. The value of simultaneous use of other hormones with testosterone has produced some discussion in the literature. The employment of estrogenic hormones in girls to achieve more physiologic development, the use of simultaneously administered thyroid and the benefit of occasional courses of the chorionic hormone in males to diminish the inhibitory effect of testosterone on the testes must be further studied. The answer to these problems may lead the way to a more promising treatment of pituitary dwarfism.

### *Obesity of Puberty*

The term "Fröhlich's syndrome" to describe the commonly seen obesity of puberty is a misnomer.<sup>52</sup> The patient described by Fröhlich had a tumor at the base of the skull associated with obesity, retarded growth and hypogenitalism. This syndrome is said to be excessively rare: of 140 cases of obesity in puberty reported,<sup>53</sup> not one was a true Fröhlich's. The present tendency is to discard this eponym and divide the obesity problem of puberty into two groups.

It is essential to rule out the very common problem of the fat, overgrown child at puberty. There is often a familial history of obesity, and the condition is equally common in both sexes. The child is often precociously bright and has a smooth, moist skin and obesity of the trunk and mammary glands, with slender extremities. The basal metabolic rate and glucose-tolerance tests are not abnormal, bone development is normal or advanced, and sexual maturity appears at the usual time or earlier.<sup>54-57</sup> These children are often not much concerned about their difficulties and have few subjective complaints, but they are usually overprotected, infantile personalities. This disorder is not regarded as primarily endocrine in nature. It may be due to simple overeating or, as has been theorized, to a functional disorder of the hypothalamus leading to excessive fat deposition. The essential treatment includes diet and psychotherapy, partly of the parents.

The situation in this type of child, however, is not infrequently complicated by a marked retardation of sexual development and sometimes by undescended testes, and the problem then becomes one of a true adiposogenital dystrophy. Such patients may or may not have retardation of bone age and bone growth, a low basal metabolism and a high sugar tolerance. In unpublished work from this laboratory,<sup>58</sup> they all show low excretion rates of the hormones of their sex. Such children represent difficult problems concerning the extensiveness of therapy, for a large percentage of them develop normally later without treatment<sup>59</sup> or may mature promptly with only a reduction of their obesity. Some of them, however, remain sexually underdeveloped and fat, and these represent a serious therapeutic problem.

Treatment should always be dietary, rarely hormonal, because the eventual appearance of sexual maturity is apt to be associated with a spontaneous loss of weight and disappearance of the syndrome. It is not the function of this review to discuss dietetic therapy, but the occasional appearance of hypoglycemia must not be neglected.<sup>60</sup> Aids to diet are amphetamine (Benzedrine) and thyroid. In our experience, thyroid is of considerable help, for

it tends to increase vigor and activity; the suggestion, however, that it may stimulate the appetite out of proportion to its beneficial effects does not conform to our experience. If rapid alteration is indicated, the gonadotropins and testosterone, alone and in combination, have been used with success.<sup>61</sup> A similar type of functional obesity may develop after pregnancy or the menopause.

The second category includes the obese patient with a hypothalamic lesion due to trauma, inflammatory disease, vascular lesions or tumors at the base of the skull or midbrain.<sup>53</sup> The patient may appear similar to those with functional obesity, but in childhood he is usually smaller and has retarded bone development and stigmas of his particular cranial lesion. Treatment obviously consists in combating the etiologic factor, together with dietary and endocrine measures. In all cases of obesity, organic lesions must be carefully ruled out.

### *Anorexia Nervosa*

Increasing attention has been given to anorexia nervosa in recent years.<sup>62-64</sup> Attempts to differentiate anorexia nervosa and Simmonds's disease have been difficult, since it is agreed generally that the starvation regimen of anorexia nervosa leads to a secondary hypopituitarism that ends with a clinical picture almost indistinguishable from that of Simmonds's disease.<sup>65</sup> However, recent work has shown that in anorexia nervosa, although the estrogens fall to a level analogous to that of childhood or Simmonds's disease, the urinary excretion of 17-ketosteroids is not markedly altered.<sup>66</sup> This appears to be an excellent differential technic to establish the diagnosis, since both components fall in Simmonds's disease.<sup>67</sup>

The basis of the therapeutic approach in anorexia nervosa is said to be psychiatric.<sup>68</sup> An analysis of the patient's background and personality, with therapeutic conferences and situational adjustments, may result in the resumption of proper eating. Close attention to the diet is essential, for only high-calorie food should be allowed, and it is occasionally advisable to insist that the patient eat more than is desired. When the appetite returns, the patient may eat astonishing amounts of food and weight gain is rapid, but recovery does not necessarily mean cure, for recurrences are not uncommon. In women, the menses may not return for several years. Younger patients are usually easier to treat, and the longer the illness the more guarded the prognosis. Intercurrent infections are dangerous.

The use of endocrine preparations is of questionable value. Thyroid appears to be detrimental by enhancing the emaciation and thus burning up more tissue. Insulin may be used to stimulate the appetite but, since insulin sensitivity may be pres-

ent, must be given cautiously. Pituitary extracts are ineffective. The use of vitamin supplements, although not specific, is of value.

The production of intermediate degrees of hypopituitarism, by temporary dieting, in people with labile endocrine systems is worthy of note. A patient who four years previously lost 40 pounds in four months by dieting, which she has since regained, but who has remained amenorrheic is a case in point.

### *Simmonds's Disease*

Destructive lesions of the anterior pituitary gland, usually due to surgical procedures, trauma, tumors or granulomas, hemorrhage, diffuse fibrosis or post partum necrosis, occasionally result in Simmonds's disease.<sup>69</sup> Necrosis of the anterior pituitary gland following a difficult puerperium with hemorrhage is the commonest etiology<sup>70</sup> of this very rare disease. In post partum pituitary necrosis, the patient may die promptly, even if vigorously treated, or may develop a chronic hypopituitarism with a low basal metabolic rate, a low blood sugar, amenorrhea, anemia, loss of body hair, apathy, asthenia and precocious senility, and usually cachexia, although this is not an essential feature. Another pregnancy, if possible, permits pituitary regeneration, and the patient may become improved.<sup>76</sup>

Patients with Simmonds's disease run a variable course,<sup>71</sup> termination usually depending on the causative agent or an intercurrent infection, for even complete hypophysectomy is not necessarily fatal.<sup>72</sup> Most of the findings in hypopituitarism are related to atrophy of the endocrine organs maintained by the pituitary gland. Although it is obviously desirable to treat the cause of the pituitary destruction, substitutive therapy for the peripheral glands is usually the only course available. Although these may not be very successful, a program should be carefully worked out and varied for the needs of each patient. Anterior pituitary extract is of no great value, but favorable results have been reported with chorionic hormone.<sup>73</sup> Estrogens and androgens, used separately, may be of help. Adrenocortical insufficiency is often present, and a high-salt diet with desoxycorticosterone is used to combat this condition.<sup>74</sup> Although hypothyroidism exists, thyroid must be given cautiously, since it may accentuate an adrenocortical insufficiency.<sup>75</sup> Hypoglycemia occurs commonly,<sup>76</sup> and frequent feedings may be necessary.

### *Acromegaly*

Acromegaly has a long and progressive course, with spontaneous remissions and exacerbations. Irradiation of the pituitary gland has received much favorable comment recently, and it is said

that it produces relief of some of the troublesome symptoms, such as the severe headaches and eye changes, and some slowing in the progression of permanent changes and the occurrence of complications.<sup>77-78</sup> Exacerbations may necessitate several courses of treatment, and the prognosis is always guarded.

Complications are common. Diabetes mellitus occurs in 17 per cent of the cases on an average of nine years after the onset of acromegaly.<sup>79</sup> Contrary to the usual statements, the diabetes is not more difficult to control than the usual type. Cardiac enlargement and failure develop with surprising frequency in one series, 18 of 24 patients had heart failure.<sup>80</sup> The cause was not clear, but the abnormality responded to the usual treatment. It is well known that macrosplinchina develops in acromegaly, but whether the heart enlarges because of a specific action of the pituitary gland or because of increased work is debatable, and this type of heart disease merits further study. Enlargement of the thyroid gland and elevation of the basal metabolic rate are common. This type of hyperthyroidism is unusual in that response to iodine is not spectacular, thyroid surgery is hazardous, and postoperatively the fall in basal metabolism is not marked.<sup>81</sup> However, if hyperthyroidism is a persistent symptom, subtotal thyroidectomy is advisable, since it may aid or prevent diabetes or heart failure. There have been no recent favorable reports on the use of sex hormones to inhibit pituitary activity in this disease.

### *Cushing's Disease*

Great efforts to distinguish between Cushing's disease (pituitary basophilism) and hyperadrenocorticalism due to primary adrenal neoplasms or hyperplasia are proceeding.<sup>82-84</sup> Attempts to differentiate these two conditions have been rather uncertain because of the pleomorphic character of the syndromes and the intermediate pictures described.<sup>85</sup> This situation is due in large part to the striking differences attributable to the sex and the age of the patient at the onset of the disease. Cushing's disease is regarded as a primary basophilic adenoma of the pituitary gland, which probably exerts its effects by stimulating the adrenal cortex to produce excessive amounts and abnormal types of steroid hormones. This results, in the adult, in the frequently described picture of hirsutism, obesity, painful striae, hypertension, diabetes, osteoporosis, rubicundity and weakness. There is an absence of virilizing effects, and the 17 ketosteroid excretion in the urine is not markedly elevated, in young people bone development may be retarded. These findings may serve to distinguish Cushing's disease from primary hyperadrenocorticalism.

In general, the successes attending the irradiation of the pituitary gland in Cushing's disease

have been only rarely conspicuous. In a recent report from Albright's<sup>86</sup> laboratory, remarkable results have been obtained by the use of testosterone propionate. This was given in 25-mg. doses every other day, and the patients developed immediate nitrogen and phosphorus retention, urinary calcium output decreased, and there were gains in weight and strength. These findings were reversed when treatment was stopped or estrogens were administered. This appears to be a most promising type of treatment on theoretical and practical grounds, and merits extensive trial. In another report, the use of Stilbestrol was reported as beneficial.<sup>87</sup>

### *Gonadal Dysfunction*

It is generally agreed that many gonadal dysfunctions are primarily of pituitary origin, yet it is not the pituitary but the steroid hormones that are being used extensively in these endocrine problems. It would be of extreme advantage, however, to have a more physiologic method of stimulating the ovaries, either to induce the normal sequence of events in the menstrual cycle or to act at a given point in the cycle, such as to induce follicle formation or to cause ovulation in the formed follicles or luteinization of the follicle cysts. The immense literature on this subject was recently reviewed,<sup>88</sup> but the conclusions regarding the pituitary hormones can be simply restated, since results are so discouraging or equivocal. Chorionic hormone alone is of no value.<sup>24, 89</sup> Pregnant-mare serum has been reported to induce ovulation, chiefly by intravenous administration,<sup>90</sup> but this must be a rare phenomenon.<sup>91-93</sup> Purified pituitary gonadotropic substances are just coming into use. It is quite obvious that women do not respond to these substances in a way analogous to the reactions of laboratory animals.

The ovaries of a large group of patients after the injection of various gonadotropic substances, alone and in combination, were studied.<sup>94</sup> The results were variable, and the desired effect was rarely obtained. Ovulation is a delicately controlled mechanism, resulting only from the appropriate balance of hormones present at the propitious moment. The dosage, time, duration, sequence and route of administration and proper combination of hormones must be observed. It is also quite obvious that diseased ovaries will not respond to the same stimulus as normal ones. Attempts to strike the necessary balance are crude as yet, but two therapeutic approaches are suggested. The use of the chorionic hormone in combination with the pituitary synergic principle has been successful in inducing ovulation.<sup>23, 95, 96</sup> The sequential use of pregnant-mare serum (400 to 800 international units daily) for the first ten days of the menstrual cycle, followed by chorionic hor-

mone (500 to 750 international units daily) for the next ten days, is reported to have given a progestational endometrium in 15 of 29 cases.<sup>97</sup> These combined treatments seem worthy of trial in anovulatory cycles. The administration of small stimulating doses of estrogens in combination with the gonadotropins is believed to increase their effectiveness.<sup>88</sup>

### *Cryptorchidism*

The usefulness of the gonadotropic hormones in the treatment of undescended testes has been clearly defined.<sup>98, 99</sup> It is effective only in cases in which no mechanical obstruction to descent exists, and these testes would probably descend at puberty of their own accord. However, in cryptorchidism, a trial with the chorionic hormone is advisable, since the testes may come down, and if not, they are enlarged so that surgery is facilitated. Pseudocryptorchidism must be carefully ruled out. The testes that are lower in the inguinal canal are the likeliest to respond to therapy.

There is some disagreement concerning whether treatment should be started just before puberty or in childhood. The tendency is to start at an early age, since premature closure of the epiphyses or enlargement of the genitalia is not a likely complication of the therapy.<sup>100</sup> The usual course of treatment is 100 to 500 international units of chorionic hormone three to six times weekly for eight or nine weeks. About 20 to 25 per cent of the cases are benefited; the rest should then be treated surgically. The administration of 5 to 10 mg. of testosterone propionate along with the chorionic hormone is said to give improvement in cases in which each hormone has failed when given separately.<sup>101</sup> The disadvantages of using testosterone in children must be considered.

### *Diabetes Mellitus*

The interest in the role of the pituitary gland in diabetes received considerable impetus from Young's discovery that chronic diabetes could be induced in dogs by long-continued injections of anterior pituitary extracts.<sup>102</sup> Insulin, if given along with this extract, or shortly afterward, prevents or cures the diabetes. If the diabetes has existed for several months, insulin has no curative effect. From this was evolved the principle that the pancreas is susceptible to complete exhaustion, but if rested early, it can be revived. It has therefore been suggested that human diabetes be treated early and intensively with a low-carbohydrate, low-calorie diet and insulin, under conditions that tend to rest the pancreas.<sup>103</sup>

The significance of the pituitary gland in the usual type of human diabetes is uncertain. In the hyperpituitarism of acromegaly, it is a late and not

an extremely frequent complication.<sup>79</sup> Although favorable results have been reported,<sup>101</sup> in general the use of estrogens in the treatment of diabetes by suppressing pituitary function has been discouraging.<sup>102, 103</sup> These recent findings, however, have proved most stimulating, and further study is needed of the relation of the pituitary gland to human diabetes.

### Hyperthyroidism

With the well-recognized dependence of the normal thyroid gland on the thyrotropic hormone of the pituitary gland, attempts have been made to attribute Graves's disease, to pituitary overactivity. The hyperthyroidism of acromegaly may be on this basis, but there is no satisfactory evidence that the usual case of Graves's disease has a similar etiology. Occasional and inconstant successes in the treatment of hyperthyroidism have been reported by the use of estrogenic substances<sup>107</sup> and chorionic hormone.<sup>108</sup> These studies, as representing a medical approach to the treatment of hyperthyroidism, are interesting but of no general therapeutic moment as yet.

An unusual subgroup of Graves's disease, referred to as "malignant exophthalmos," is being stressed by Means and his group.<sup>109</sup> In these patients, the exophthalmos is profound, although the basal metabolic rate is only slightly elevated, if at all. This exophthalmos is probably due to large excesses of thyrotropic hormone, which is reported to cause a specific hypertrophy, edema and lymphocytic infiltration of the extraocular muscles.<sup>110</sup> This condition must be carefully differentiated from ordinary exophthalmic goiter, since in the former, thyroidectomy may prove disastrous by increasing the exophthalmos until blindness results. The appropriate treatment, therefore, in the selected case is to attempt to suppress the pituitary overactivity. This consists in the use of nodules and thyroid in a balanced combination to depress the basal metabolic rate and to inhibit pituitary activity. Estrogens are worth trying. If the exophthalmos progresses, x-ray treatment to the pituitary gland and to the orbit may help,<sup>111</sup> and as a last resort, if vision is menaced, orbital decompression may be indicated. If the hyperthyroidism requires treatment, x-ray therapy to the thyroid gland is preferred. Surgery, if used, requires the most considered preoperative and postoperative care.

\* \* \*

To summarize this mass of new work is difficult. It may be stated, however, that the importance of the pituitary gland is fairly well established in many abnormalities of the endocrine glands. Even though it may frequently be the

primary factor, the use of pituitary hormones has, on the whole, been disappointing in therapeutic effects. This is due to the difficulties in obtaining adequate sources and in purification. It is also unwise to use continuous therapy because of the temporary immunity produced by injected pituitary hormones, so that intermittent therapy is imposed. As a result, pituitary deficiencies are now more effectively treated by the use of endocrine hormones derived from the peripheral glands

## CASE 28191

### PRESENTATION OF CASE

A fifty-four-year-old Italian housewife was admitted to the hospital because of pain in the right shoulder blade.

The patient was in good health until seven months before entry, when she began to lose weight and developed a dull aching pain in the area of the right shoulder blade. The pain was not related to meals, exertion, posture or time of day. It varied greatly in intensity, sometimes remitting completely. At times, it radiated down the right arm to the hand, and on other occasions it extended to the left shoulder blade. Throughout the illness, there were transient periods of low fever, with occasional chills and night sweats. At times, there was a slight cough. Strength and weight were progressively lost, the latter to the extent of 27 pounds during the illness. Nine months before entry, the menses (previously regular) ceased. Slight nasal bleeding occurred at the times of some of the expected periods. The appetite became poor early in the illness. Gaseous eructations, unaccompanied by nausea or vomiting, frequently followed meals. Concomitantly, the patient's previous bowel regularity was replaced by alternating bouts of constipation and diarrhea. Borborygmi and griping lower abdominal pains accompanied the constipation, whereas the alternating periods of four or five watery stools a day were painless. The patient had worked in a chocolate factory until four years before entry. She was accustomed to a glass of wine with meals. The past and family histories were irrelevant.
